Sir Stanley Davidson (1894–1981)
This famous textbook was the brainchild of one of the great Professors of Medicine of the 20th century. Stanley Davidson was born in Sri Lanka and began his medical undergraduate training at Trinity College, Cambridge; this was interrupted by World War I and later resumed in Edinburgh. He was seriously wounded in battle, and the carnage and shocking waste of young life that he encountered at that time had a profound effect on his subsequent attitudes and values.

In 1930 Stanley Davidson was appointed Professor of Medicine at the University of Aberdeen, one of the first full-time Chairs of Medicine anywhere and the first in Scotland. In 1938 he took up the Chair of Medicine at Edinburgh and was to remain in this post until retirement in 1959. He was a renowned educator and a particularly gifted teacher at the bedside, where he taught that everything had to be questioned and explained. He himself gave most of the systematic lectures in Medicine, which were made available as typewritten notes that emphasised the essentials and far surpassed any textbook available at the time. 

Principles and Practice of Medicine was conceived in the late 1940s with its origins in those lecture notes. The first edition, published in 1952, was a masterpiece of clarity and uniformity of style. It was of modest size and price, but sufficiently comprehensive and up to date to provide students with the main elements of sound medical practice. Although the format and presentation have seen many changes in 22 subsequent editions, Sir Stanley’s original vision and objectives remain. More than half a century after its first publication, his book continues to inform and educate students, doctors and health professionals all over the world.
Davidson’s Principles and Practice of Medicine

23rd Edition

Preface

Well over two million copies of Davidson’s Principles and Practice of Medicine have been sold since it was first published in 1952. Now in its 23rd Edition, Davidson’s is regarded as a ‘must-have’ textbook for thousands of medical students, doctors and health professionals across the world, describing the pathophysiology and clinical features of the most important conditions encountered in the major specialties of adult medicine and explaining how to investigate, diagnose and manage them. The book is the winner of numerous prizes and awards and has been translated into many languages. Taking its origins from Sir Stanley Davidson’s much-admired lecture notes, the book has endured because it continues to keep pace with how modern medicine is taught and to provide a wealth of information in an easy-to-read, concise and beautifully illustrated format.

Davidson’s strives to ensure that readers can not only recognise the clinical features of a disease but also understand the underlying causes. To achieve this, each chapter begins with a summary of the relevant pre-clinical science, linking pathophysiology with clinical presentation and treatment so that students can use the book from the outset of their medical studies right through to their final examinations and beyond.

The regular introduction of new authors and editors is important for maintaining freshness. On this occasion, Professor Mark Strachan and Dr Richard Hobson have come on board as editors, and 26 new authors have joined our existing contributors to make up an outstanding team of authorities in their respective fields. As well as recruiting authors from around the globe, particularly for topics such as infectious diseases, HIV and envenomation, we welcome members from 17 countries on to our International Advisory Board. These leading experts provide detailed comments that are crucial to our revision of each new edition. A particularly important aspect in planning the revision is for the editors to meet students and faculty in medical schools in those countries where the book is most widely read, so that we can respond to the feedback of our global readership and their tutors. We use this feedback, along with the information we gather via detailed student reviews and surveys, to craft each edition. The authors, editors and publishing team aim to ensure that readers all over the world are best served by a book that integrates medical science with clinical medicine to convey key knowledge and practical advice in an accessible and readable format. The amount of detail is tailored to the needs of medical students working towards their final examinations, as well as candidates preparing for Membership of the Royal Colleges of Physicians (MRCP) or its equivalent.

With this new edition we have introduced several changes in both structure and content. The opening six chapters provide an account of the principles of genetics, immunology, infectious diseases and population health, along with a discussion of the core principles behind clinical decision-making and good prescribing. Subsequent chapters discuss medical emergencies in poisoning, envenomation and environmental medicine, while a new chapter explores common presentations in acute medicine, as well as the recognition and management of the critically ill. The disease-specific chapters that follow cover the major medical specialties, each one thoroughly revised and updated to ensure that readers have access to the ‘cutting edge’ of medical knowledge and practice. Two new chapters on maternal and adolescent/transition medicine now complement the one on ageing and disease, addressing particular problems encountered at key stages of patients’ lives. Medical ophthalmology is also now included as a direct response to readers’ requests.

The innovations introduced in recent editions have been maintained and, in many cases, developed. The highly popular ‘Clinical Examination’ overviews have been extended to the biochemistry, nutrition and dermatology chapters. The ‘Presenting Problems’ sections continue to provide an invaluable overview of the most common presentations in each disease area. The ‘Emergency’ and ‘Practice Point’ boxes have been retained along with the ‘In Old Age’, ‘In Pregnancy’ and ‘In Adolescence’ boxes, which emphasise key practical points in the presentation and management of the elderly, women with medical disorders who are pregnant or planning pregnancy, and teenagers transitioning between paediatric and adult services.

Education is achieved by assimilating information from many sources and readers of this book can enhance their learning experience by using several complementary resources. We are delighted to have a new self-testing companion book entitled Davidson’s Assessment in Medicine, containing over 1250 multiple choice questions specifically tailored to the contents of Davidson’s. The long-standing association of Davidson’s with its sister books, Macleod’s Clinical Examination (now in its 14th Edition) and Principles and Practice of Surgery (7th Edition), still holds good. Our ‘family’ has also expanded with the publication of Davidson’s Essentials of Medicine, a long-requested pocket-sized version of the main text; Davidson’s 100 Clinical Cases, which contains scenarios directly based on our ‘Presenting Problems’; and Macleod’s Clinical Diagnosis, which describes a systematic approach to the differential diagnosis of symptoms and signs. We congratulate the editors and authors of these books for continuing the tradition of easily digested and expertly illustrated texts.

We all take immense pride in continuing the great tradition first established by Sir Stanley Davidson and in producing an outstanding book for the next generation of doctors.

Acknowledgements

Following the publication of the 22nd edition of Davidson's, Professor Brian Walker and Dr Nicki Colledge retired as editors. We would like to express our gratitude for the immense contribution they both made to the continuing success of this textbook.

The current editors would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible. In particular we are indebted to those former authors who stepped down with the arrival of this new edition. They include Assistant Professor Alirunri Ryan Abdul-Razak, Professor Andrew Bradbury, Dr Jenny Craig, Professor Allan Cumming, Dr Robert Dawe, Emeritus Professor Michael Field, Dr Jane Goddard, Professor Philip Hanlon, Dr Charlie Lees, Dr Helen Macdonald, Professor Iain McInnes, Dr Graham Nimmo, Dr Simon Noble, Dr David Oxenham, Professor Jonathan Seckl, Professor Michael Sharpe, Professor Neil Turner, Dr Simon Walker and Professor Timothy Walsh.

We are grateful to members of the International Advisory Board, all of whom provided detailed suggestions that have improved the book. Several members have now retired from the Board and we are grateful for their support during the preparation of previous editions. They include Professor OC Abraham, Professor Toayfel Ahmed, Professor Samar Banerjee, Professor Tapas Das, Professor Tsuguya Fukui, Professor Saman Gunatiak, Professor Wasim Jafri, Professor Saradave Naicker, Professor Nardeep Nathani, Professor Prem Pais, Professor A Ramachandran, the late Professor (Mrs) Harsha R Salkar and Professor Subhash Varma.

Detailed chapter reviews were commissioned to help plan this new edition and we are grateful to all those who assisted, including Professor Rustam Al-Shahi, Dr David Enoch, Dr Colin Forfar, Dr Richard Herriot and Dr Robert Lindsay.

The Editors and Publisher would like to thank all those who have provided valuable feedback on this textbook and whose comments have helped shape this new edition. We would particularly like to extend our thanks to the many readers who contact us with suggestions for improvements. This input has been invaluable and is much appreciated; we regret the names of too many to mention individually.

The authors of Chapter 20 would like to thank Dr Drew Henderson, who reviewed the ‘Diabetic nephropathy’ section. Two short sections in Chapter 3 on array comparative genomic hybridisation and single-molecule sequencing are adapted from Dr K Tatton-Brown’s Massive Open Online Course for FutureLearn. We would like to thank the Open University and St George’s, University of London, for permission to use this material.

We are especially grateful to all those working for Elsevier, in particular Laurence Hunter, Wendy Lee and Robert Britton, for their endless support and expertise in the shaping, collation and illustration of this edition.

SHR, IDP, MWJS, RPH
Edinburgh 2018
The opening six chapters of the book, making up Part 1 on ‘Fundamentals of Medicine’, provide an account of the principles of genetics, immunology, infectious diseases and population health, along with a discussion of the core principles behind clinical decision-making and good prescribing. Subsequent chapters in Part 2, ‘Emergency and Critical Care Medicine’, discuss medical emergencies in poisoning, envenomation and environmental medicine, while a new chapter explores common presentations in acute medicine, as well as the recognition and management of the critically ill. The third part, ‘Clinical Medicine’, is devoted to the major medical specialties. Each chapter has been written by experts in the field to provide the level of detail expected of trainees in their discipline. To maintain the book’s virtue of being concise, care has been taken to avoid unnecessary duplication between chapters.

The system-based chapters in Part 3 follow a standard format, beginning with an overview of the relevant aspects of clinical examination, followed by an account of functional anatomy, physiology and investigations, then the common presentations of disease, and details of the individual diseases and treatments relevant to that system. In chapters that describe the immunological, cellular and molecular basis of disease, this problem-based approach brings the close links between modern medical science and clinical practice into sharp focus.

The methods used to present information are described below.

**Clinical examination overviews**

The value of good clinical skills is highlighted by a two-page overview of the important elements of the clinical examination at the beginning of most chapters. The left-hand page includes a mannikin to illustrate key steps in examination of the relevant system, beginning with simple observations and progressing in a logical sequence around the body. The right-hand page expands on selected themes and includes tips on examination technique and interpretation of physical signs. These overviews are intended to act as an aide-mémoire and not as a replacement for a detailed text on clinical examination, as provided in our sister title, *Macleod’s Clinical Examination*.

**Presenting problems**

Medical students and junior doctors must not only assimilate a great many facts about various disorders but also develop an analytical approach to formulating a differential diagnosis and a plan of investigation for patients who present with particular symptoms or signs. In *Davidson’s* this is addressed by incorporating a ‘Presenting Problems’ section into all relevant chapters. Nearly 250 presentations are included, which represent the most common reasons for referral to each medical specialty.

**Boxes**

Boxes are a popular way of presenting information and are particularly useful for revision. They are classified by the type of information they contain, using specific symbols.

- **General Information**
  These include causes, clinical features, investigations, treatments and other useful information.

- **Practice Point**
  These are many practical skills that students and doctors must master. These vary from inserting a nasogastric tube to reading an ECG or X-ray, or interpreting investigations such as arterial blood gases or thyroid function tests. ‘Practice Point’ boxes provide straightforward guidance on how these and many other skills can be acquired and applied.

- **Emergency**
  These boxes describe the management of many of the most common emergencies in medicine.

- **In Old Age**
  In many countries, older people comprise 20% of the population and are the chief users of health care. While they contract the same diseases as those who are younger, there are often important differences in the way they present and how they are best managed. Chapter 32, ‘Ageing and disease’, concentrates on the principles of managing the frailest group who suffer from multiple comorbidity and disability, and who tend to present with non-specific problems such as falls or delirium. Many older people, though, also suffer from specific single-organ pathology. ‘In Old Age’ boxes are thus included in each chapter and describe common presentations, implications of physiological changes of ageing, effects of age on investigations, problems
INTRODUCTION

treatment in old age, and the benefits and risks of intervention in older people.

In Pregnancy

Many conditions are different in the context of pregnancy, while some arise only during or shortly after pregnancy. Particular care must be taken with investigations (for example, to avoid radiation exposure to the fetus) and treatment (to avoid the use of drugs that harm the fetus). These issues are highlighted by ‘In Pregnancy’ boxes distributed throughout the book, which complement the new chapter on maternal medicine.

In Adolescence

Although paediatric medicine is not covered in Davidson’s, many chronic disorders begin in childhood and adult physicians often contribute to multidisciplinary teams that manage young patients ‘in transition’ between paediatric and adult health-care services. This group of patients often presents a particular challenge, due to the physiological and psychological changes that occur in adolescence and which can have a major impact on the disease and its management. Adolescents can be encouraged to take over responsibility from their parents/carers in managing their disease, but are naturally rebellious and often struggle to adhere to the impositions of chronic treatment. To highlight these issues, we have introduced a new chapter on adolescent and transition medicine to accompany the ‘In Adolescence’ boxes that appear in relevant chapters.

Terminology

The recommended International Non-proprietary Names (INNs) are used for all drugs, with the exception of adrenaline and noradrenaline. British spellings have been retained for drug classes and groups (e.g. amphetamines not amfetamines).

Units of measurement

The International System of Units (SI units) is the recommended means of presentation for laboratory data and has been used throughout Davidson’s. We recognise, though, that many laboratories around the world continue to provide data in non-SI units, so these have been included in the text for the commonly measured analytes. Both SI and non-SI units are also given in Chapter 35, which describes the reference ranges used in Edinburgh’s laboratories. It is important to appreciate that these reference ranges may vary from those used in other laboratories.

Finding what you are looking for

A contents list is given on the opening page of each chapter. In addition, the book contains numerous cross-references to help readers find their way around, along with an extensive index. A list of up-to-date reviews and useful websites with links to management guidelines appears at the end of each chapter.

Giving us your feedback

The Editors and Publisher hope that you will find this edition of Davidson’s informative and easy to use. We would be delighted to hear from you if you have any comments or suggestions to make for future editions of the book. Please contact us by e-mail at: davidson.feedback@elsevier.com. All comments received will be much appreciated and will be considered by the editorial team.
Clinical decision-making

Diagnosis error has been defined as ‘a situation in which the clinician has all the information necessary to make the diagnosis but then makes the wrong diagnosis’. Why does this happen?

Studies reveal three main reasons:

• knowledge gaps
• misinterpretation of diagnostic tests
• cognitive biases.

Examples of errors in these three categories are shown in Box 1.2.

Clearly, clinical knowledge is required for sound clinical reasoning, and an incomplete knowledge base or inadequate experience can lead to diagnostic error. However, this chapter focuses on other elements of clinical reasoning: namely, the interpretation of diagnostic tests, cognitive biases and human factors.

Clinical reasoning: definitions

‘Clinical reasoning’ describes the thinking and decision-making processes associated with clinical practice. It is a clinician’s ability to make decisions (often with others) based on all the available clinical information, starting with the history and physical examination. Our understanding of clinical reasoning derives from the fields of education, cognitive psychology and studies of expertise.

Figure 1.1 shows the different elements involved in clinical reasoning. Good clinical skills are fundamental, followed by understanding how to use and interpret diagnostic tests. Other essential elements include an understanding of cognitive biases and human factors, and the ability to think about one’s own thinking (which is explained in more detail later). Other key elements of clinical reasoning include patient-centred evidence-based medicine (EBM) and shared decision-making with patients and/or carers.

| 1.1 Root causes of diagnostic error in studies |
|-----------------------------|------------------|
| Error category | Examples |
| No fault | Unusual presentation of a disease Missing information |
| System error | Inadequate diagnostic support Results not available Error-prone processes Poor supervision of inexperienced staff Poor team communication |
| Human cognitive error | Inadequate data-gathering Errors in reasoning |

| 1.2 Reasons for errors in clinical reasoning |
|-----------------------------|------------------|
| Source of error | Examples |
| Knowledge gaps | Telling a patient she cannot have biliary colic because she has had her gallbladder removed – gallstones can form in the bile ducts in patients who have had a cholecystectomy |
| Misinterpretation of diagnostic tests | Deciding a patient has not had a stroke because his brain scan is normal – computed tomography and even magnetic resonance imaging, especially when performed early, may not identify an infarct |
| Cognitive biases | Accepting a diagnosis handed over to you without question (the ‘framing effect’) instead of asking yourself ‘What is the evidence that supports this diagnosis?’ |

Diagnostic error is estimated to be 10–15% of the time in specialties such as emergency medicine, internal medicine and general practice. Diagnostic error is associated with greater morbidity than other types of medical error, and the majority is considered to be preventable. For every diagnostic error there are a number of root causes. Studies of misdiagnosis assign three main categories, shown in Box 1.1; however, errors in clinical reasoning play a significant role in the majority of diagnostic adverse events.

Fig. 1.1 Elements of clinical reasoning. (EBM = evidence-based medicine)
Clinical skills and decision-making

Even with major advances in medical technology, the history remains the most important part of the clinical decision-making process. Studies show that physicians make a diagnosis in 70–90% of cases from the history alone. It is important to remember that a good history is gathered not only from the patient but also, if necessary (and with consent if required), from all available sources: for example, paramedic and emergency department notes, eye-witnesses, relatives and/or carers.

Clinicians need to be aware of the diagnostic usefulness of clinical features in the history and examination. For example, students are taught that meningitis presents with the following features:
- headache
- fever
- meningism (photophobia, nuchal rigidity).

However, the frequency with which patients present with certain features and the diagnostic weight of each feature are important in clinical reasoning. For example, many patients with meningitis do not have classical signs of meningeal irritation (Kernig’s sign, Brudzinski’s sign and nuchal rigidity). In one prospective study, they had likelihood ratios of around 1, meaning they carried little diagnostic weight (Fig. 1.2).

Likelihood ratios (LR) are clinical diagnostic weights. An LR of greater than 1 increases the probability of disease (the higher the value, the greater the probability). Similarly, an LR of less than 1 decreases the probability of disease. LRs are developed against a diagnostic standard (e.g., in the case of meningitis, lumbar puncture results), so do not exist for all clinical findings. LRs illustrate how an individual clinical finding changes the probability of a disease. For example, in a person presenting with headache and fever, the clinical finding of nuchal rigidity (neck stiffness) may carry little weight in deciding whether to perform a lumbar puncture because LRs do not determine the prior probability of disease; they reflect only how a single clinical finding changes it. Clinicians have to take all the available information from the history and physical examination into account. If the overall clinical probability is high to begin with, a clinical finding with an LR of around 1 does not change this.

"Evidence-based history and examination" is a term used to describe how clinicians incorporate knowledge about the prevalence and diagnostic weight of clinical findings into their history and physical examination. This is important because an estimate of clinical probability is vital in decision-making and the interpretation of diagnostic tests.

Use and interpretation of diagnostic tests

There is no such thing as a perfect diagnostic test. Test results give us test probabilities, not real probabilities. Test results have to be interpreted because they are affected by the following:
- how ‘normal’ is defined
- factors other than disease
- operating characteristics
- sensitivity and specificity
- how ‘normal’ is defined
- prevalence of disease in the population.

Normal values

Most tests provide quantitative results (i.e., a value on a continuous numerical scale). In order to classify quantitative results as normal or abnormal, it is necessary to define a cut-off point. Many quantitative measurements in populations have a Gaussian or ‘normal’ distribution. By convention, the normal range is defined as those values that encompass 95% of the population, or 2 standard deviations above and below the mean. This means that 2.5% of the normal population will have values above, and 2.5% will have values below the normal range. For this reason, it is more appropriate to talk about the ‘reference range’ rather than the ‘normal range’ (Fig. 1.3).

Test results in abnormal populations also have a Gaussian distribution, with a different mean and standard deviation. In some diseases there is no overlap between results from the abnormal and normal population. However, in many diseases there is overlap; in these circumstances, the greater the difference between the test result and the limits of the reference range, the higher the chance that the person has a disease.

However, there are also situations in medicine when ‘normal’ is abnormal and ‘abnormal’ is normal. For example, a normal 

\[ \text{PaCO}_2 \]\n
in the context of a severe asthma attack is abnormal and means the patient has life-threatening asthma. A low ferritin in a young menstruating woman is not considered to be a disease at all. Normal, to some extent, is therefore arbitrary.
comply fully with some tests, such as spirometry (p. 569), and if to the way the test is performed. Patients need to be able to.

Tests are also subject to operating characteristics. This refers to the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean ± 2 standard deviations (SD) encompasses 95% of the normal population and usually defines the ‘reference range’; 2.5% of the normal population have values above, and 2.5% below, this range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

**Fig. 1.3 Normal distribution and reference range.** For many tests, the frequency distribution of results in the normal healthy population (red line) is a symmetrical bell-shaped curve. The mean ± 2 standard deviations (SD) encompasses 95% of the normal population and usually defines the ‘reference range’; 2.5% of the normal population have values above, and 2.5% below, this range (shaded areas). For some diseases (blue line), test results overlap with the normal population or even with the reference range. For other diseases (green line), tests may be more reliable because there is no overlap between the normal and abnormal population.

### Factors other than disease that influence test results

A number of factors other than disease influence test results:
- age
- ethnicity
- pregnancy
- sex
- spurious (in vitro) results.

Box 1.3 gives some examples.

**Box 1.3 Examples of factors other than disease that influence test results**

<table>
<thead>
<tr>
<th>Factor</th>
<th>Examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>Age</td>
<td>Creatinine is lower in old age (due to relatively lower muscle mass) – an older person can have a significantly reduced eGFR rate with a ‘normal’ creatinine</td>
</tr>
<tr>
<td>Ethnicity</td>
<td>Healthy people of African ancestry have lower white cell counts</td>
</tr>
</tbody>
</table>
| Pregnancy    | Several tests are affected by late pregnancy, due to the effects of a growing fetus, including: Reduced urea and creatinine (haemodilution) 
                                 | Iron deficiency anaemia (increased demand)                                                                                                     |
|              | Increased alkaline phosphatase (produced by the placenta)                                                                                      |
|              | Mild respiratory alkalosis (physiological changes in the coagulation system)                                                                    |
|              | ECG changes (tachycardia, left axis deviation)                                                                                                 |
| Sex          | Males and females have different reference ranges for many tests, e.g. haemoglobin                                                            |
| Spurious (in vitro) results | A spurious high potassium is seen in haemolysis and in thrombocytosis (‘pseudohyperkalaemia’)                                                   |

### Sensitivity and specificity

Diagnostic tests have characteristics termed ‘sensitivity’ and ‘specificity’. Sensitivity is the ability to detect true positives; specificity is the ability to detect true negatives. Even a very good test, with 95% sensitivity, will miss 1 in 20 people with the disease. Every test therefore has ‘false positives’ and ‘false negatives’ (Box 1.4).

A very sensitive test will detect most disease but generate abnormal findings in healthy people. A negative result will therefore reliably exclude disease but a positive result does not mean the disease is present – it means further evaluation is required. On the other hand, a very specific test may miss significant pathology but is likely to establish the diagnosis beyond doubt when the result is positive. All tests differ in their sensitivity and specificity, and clinicians require a working knowledge of the tests they use in this respect.

In choosing how a test is used to guide decision-making there is a trade-off between sensitivity versus specificity. For example, defining an exercise electrocardiogram (p. 449) as abnormal if there is at least 0.5 mm of ST depression would ensure that very few cases of coronary artery disease are missed but would generate many false-positive results (high sensitivity, low specificity). On the other hand, a cut-off point of 2.0 mm of ST depression would detect most cases of important coronary artery disease with far fewer false positives. This trade-off is illustrated by the receiver operating characteristic curve of the test (Fig. 1.4).

An extremely important concept is this: the probability that a person has a disease depends on the pre-test probability, and the sensitivity and specificity of the test. For example, imagine that an elderly lady has fallen and hurt her left hip. On examination,
the hip is extremely painful to move and she cannot stand. However, her hip X-rays are normal. Does she have a fracture?

The sensitivity of plain X-rays of the hip performed in the emergency department for suspected hip fracture is around 95%. A small percentage of fractures are therefore missed. If our patient has (or is at risk of) osteoporosis, has severe pain on hip movement and cannot bear weight on the affected side, then the clinical probability of hip fracture is high. If, on the other hand, she is unlikely to have osteoporosis, has no pain on hip movement and is able to bear weight, then the clinical probability of hip fracture is low.

Doctors are continually making judgements about whether something is true, given that something else is true. This is known as ‘conditional probability’. Bayes’ Theorem (named after English clergyman Thomas Bayes, 1702–1761) is a mathematical way to describe the post-test probability of a disease by combining pre-test probability, sensitivity and specificity. In clinical practice, doctors are not able to make complex mathematical calculations for every decision they make. In practical terms, the answer to the question of whether there is a fracture is that in a high-probability patient a normal test result does not exclude the condition, but in a low-probability patient it makes it very unlikely. This principle is illustrated in Figure 1.5.

Sox and colleagues (see ‘Further information’) state a fundamental assertion, which they describe as a profound and subtle principle of clinical medicine: the interpretation of new information depends on what you believed beforehand. In other words, the interpretation of a test result depends on the probability of disease before the test.

### Prevalence of disease

Consider this problem that was posed to a group of Harvard doctors: if a test to detect a disease whose prevalence is 1:1000 has a false-positive rate of 5%, what is the chance that a person found to have a positive result actually has the disease, assuming you know nothing about the person’s symptoms and signs? Take a moment to work this out. In this problem, we have removed clinical probability and are only considering prevalence. The answer is at the end of the chapter.

Predictive values combine sensitivity, specificity and prevalence. Sensitivity and specificity are characteristics of the test; the population does not change this. However, as doctors, we are interested in the question, ‘What is the probability that a person with a positive test actually has the disease?’ This is illustrated in Box 1.5.

Post-test probability and predictive values are different. Post-test probability is the probability of a disease after taking into account new information from a test result. Bayes’ Theorem can be used to calculate post-test probability for a patient in any population. The pre-test probability of disease is decided by the doctor; it is a judgement based on information gathered prior to ordering the test. Predictive value is the proportion of patients with a test result who have the disease (or no disease) and is calculated from a table of results in a specific population (see Box 1.5). It is not possible to transfer this value to a different population. This is important to realise because published information about the performance of diagnostic tests may not apply to different populations.

In deciding the pre-test probability of disease, clinicians often neglect to take prevalence into account and this distorts their estimate of probability. To estimate the probability of disease in a patient more accurately, clinicians should anchor on the prevalence of disease in the subgroup to which the patient belongs and then adjust to take the individual factors into account.

### Dealing with uncertainty

Clinical findings are imperfect and diagnostic tests are imperfect. It is important to recognise that clinicians frequently deal with uncertainty. By expressing uncertainty as probability, new information from diagnostic tests can be incorporated more accurately. However, subjective estimates of probability can sometimes be unreliable. As the section on cognitive biases will demonstrate (see below), intuition can be a source of error.
Knowing the patient’s true state is often unnecessary in clinical decision-making. Sox and colleagues (see ‘Further information’) argue that there is a difference between knowing that a disease is present and acting as if it were present. The requirement for diagnostic certainty depends on the penalty for being wrong. Different situations require different levels of certainty before starting treatment. How we communicate uncertainty to patients will be discussed later in this chapter (p. 10).

The treatment threshold combines factors such as the risks of the test, and the risks versus benefits of treatment. The point at which the factors are all evenly weighed is the threshold. If a test or treatment for a disease is effective and low-risk (e.g. giving antibiotics for a suspected urinary tract infection), then there is a lower threshold for going ahead. On the other hand, if a test or treatment is less effective or high-risk (e.g. starting chemotherapy for a malignant brain tumour), then greater confidence is required in the clinical diagnosis and potential benefits of treatment first. In principle, if a diagnostic test will not change the management of the patient, then careful consideration should be given to whether it is necessary to do the test at all.

In summary, test results shift our thinking, but rarely give a ‘yes’ or a ‘no’ answer in terms of a diagnosis. Sometimes tests shift the probability of disease by less than we realise. Pre-test probability is key, and this is derived from the history and physical examination, combined with a sound knowledge of medicine and an understanding of the prevalence of disease in the particular care setting or the population to which the patient belongs.

Cognitive biases

Advances in cognitive psychology in recent decades have demonstrated that human thinking and decision-making are prone to error. Cognitive biases are subconscious errors that lead to inaccurate judgement and illogical interpretation of information. They are prevalent in everyday life; as the famous saying goes, ‘to err is human.’

Take a few moments to look at this simple puzzle. Do not try to solve it mathematically but listen to your intuition:

A bat and ball cost £1.10. The bat costs £1 more than the ball. How much does the ball cost?

The answer is at the end of the chapter. Most people get the answer to this puzzle wrong. Two things are going on: one is that humans have two distinct types of processes when it comes to thinking and decision-making – termed ‘type 1’ and ‘type 2’ thinking. The other is that the human brain is wired to jump to conclusions sometimes or to miss things that are obvious. British psychologist and patient safety pioneer James
Cognitive biases

A young woman was found beside her at home. Her observations show she has a Glasgow Coma Scale score of 10/15, heart rate 100 beats/min, blood pressure 100/60 mmHg, respiratory rate 14 breaths/min, oxygen saturations 98% on air and temperature 37.5°C. Already your mind has reached a working diagnosis. It fits a pattern (type 1 thinking). You think she has taken an overdose. At this point you can stop to think about your thinking (rational override in Fig. 1.6): ‘What is the evidence for this diagnosis? What else could it be?’

On the other hand, imagine being asked to assess a patient who has been admitted with syncope. There are several different causes of syncope and a systematic approach is required to reach a diagnosis (type 2 thinking). However, you recently heard about a case of syncope due to a leaking abdominal aortic aneurysm. At the end of your assessment, following evidence-based guidelines, it is clear the patient can be discharged. Despite this, you decide to observe the patient overnight ‘just in case’ (irrational override in Fig. 1.6). In this example, your intuition is actually availability bias (when things are at the forefront of your mind), which has significantly distorted your estimate of probability.

Common cognitive biases in medicine

Figure 1.7 illustrates the common cognitive biases prevalent in medical practice. Biases often work together; for example, in...
<table>
<thead>
<tr>
<th>Cognitive Bias</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Anchoring</strong></td>
<td>The common human tendency to rely too heavily on the first piece of information offered (the “anchor”) when making decisions.</td>
</tr>
<tr>
<td><strong>Diagnostic momentum</strong></td>
<td>Once a diagnostic label has been attached to a patient (by the patient or other health-care professionals), it can gather momentum with each review, leading others to exclude other possibilities in their thinking.</td>
</tr>
<tr>
<td><strong>Premature closure</strong></td>
<td>The tendency to close the decision-making process prematurely and accept a diagnosis before it, and other possibilities, have been fully explored.</td>
</tr>
<tr>
<td><strong>Ascertainment bias</strong></td>
<td>We sometimes see what we expect to see (“self-fulfilling prophecy”). For example, a frequent self-harmer attends the emergency department with drowsiness; everyone assumes he has taken another overdose and misses a brain injury.</td>
</tr>
<tr>
<td><strong>Framing effect</strong></td>
<td>How a case is presented – for example, in handover – can generate bias in the listener. This can be mitigated by always having ‘healthy scepticism’ about other people’s diagnoses.</td>
</tr>
<tr>
<td><strong>Psych-out error</strong></td>
<td>Psychiatric patients who present with medical problems are under-assessed, under-examined and under-investigated because problems are presumed to be due to, or exacerbated by, their psychiatric condition.</td>
</tr>
<tr>
<td><strong>Availability bias</strong></td>
<td>Things may be at the forefront of your mind because you have seen several cases recently or have been studying that condition in particular. For example, when one of the authors worked in an epilepsy clinic, all blackouts were possible seizures.</td>
</tr>
<tr>
<td><strong>Hindsight bias</strong></td>
<td>Knowing the outcome may profoundly influence the perception of past events and decision-making, preventing a realistic appraisal of what actually occurred – a major problem in learning from diagnostic error.</td>
</tr>
<tr>
<td><strong>Search satisficing</strong></td>
<td>We may stop searching because we have found something that fits or is convenient, instead of systematically looking for the best alternative, which involves more effort.</td>
</tr>
<tr>
<td><strong>Base rate neglect</strong></td>
<td>The tendency to ignore the prevalence of a disease, which then distorts Bayesian reasoning. In some cases, clinicians do this deliberately in order to rule out an unlikely but worst-case scenario.</td>
</tr>
<tr>
<td><strong>Omission bias</strong></td>
<td>The tendency towards inaction, rooted in the principle of ‘first do no harm.’ Events that occur through natural progression of disease are more acceptable than those that may be attributed directly to the action of the health-care team.</td>
</tr>
<tr>
<td><strong>Triage-cueing</strong></td>
<td>Triage ensures patients are sent to the right department. However, this leads to ‘geography is destiny’. For example, a diabetic ketoacidosis patient with abdominal pain and vomiting is sent to surgery. The wrong location (surgical ward) stops people thinking about medical causes of abdominal pain and vomiting.</td>
</tr>
<tr>
<td><strong>Commission bias</strong></td>
<td>The tendency towards action rather than inaction, on the assumption that good can come only from doing something (rather than ‘watching and waiting’).</td>
</tr>
<tr>
<td><strong>Overconfidence bias</strong></td>
<td>The tendency to believe we know more than we actually do, placing too much faith in opinion instead of gathered evidence.</td>
</tr>
<tr>
<td><strong>Unpacking principle</strong></td>
<td>Failure to ‘unpack’ all the available information may mean things are missed. For example, if a thorough history is not obtained from either the patient or carers (a common problem in geriatric medicine), diagnostic possibilities may be discounted.</td>
</tr>
<tr>
<td><strong>Confirmation bias</strong></td>
<td>The tendency to look for confirming evidence to support a theory rather than looking for disconfirming evidence to refute it, even if the latter is clearly present. Confirmation bias is common when a patient has been seen first by another doctor.</td>
</tr>
<tr>
<td><strong>Posterior probability</strong></td>
<td>Our estimate of the likelihood of disease may be unduly influenced by what has gone on before for a particular patient. For example, a patient who has been extensively investigated for headaches presents with a severe headache, and serious causes are discounted.</td>
</tr>
<tr>
<td><strong>Visceral bias</strong></td>
<td>The influence of either negative or positive feelings towards patients, which can affect our decision-making.</td>
</tr>
</tbody>
</table>

Fig. 1.7 Common cognitive biases in medicine. Adapted from Croskerry P. Achieving quality in clinical decision-making: cognitive strategies and detection of bias. Acad Emerg Med 2002; 9:1184–1204.
overconfidence bias (the tendency to believe we know more than we actually do), too much faith is placed in opinion instead of gathered evidence. This bias can be augmented by the availability bias and finally by commission bias (the tendency towards action rather than inaction) — sometimes with disastrous results.

The mark of a well-calibrated thinker is the ability to recognise what mode of thinking is being employed and to anticipate and recognise situations in which cognitive biases and errors are more likely to occur.

**Human factors**

‘Human factors’ is the science of the limitations of human performance, and how technology, the work environment and team communication can adapt for this to reduce diagnostic and other types of error. Analysis of serious adverse events in clinical practice shows that human factors and poor team communication play a significant role when things go wrong.

Research shows that many errors are beyond an individual’s conscious control and are precipitated by many factors. The discipline of human factors seeks to understand interactions between:

- people and tasks or technology
- people and their work environment
- people in a team.

An understanding of these interactions makes it easier for health-care professionals, who are committed to ‘first do no harm,’ to work in the safest way possible. For example, performance is adversely affected by factors such as poorly designed processes and equipment, frequent interruptions and fatigue. The areas of the brain required for type 2 processing are most affected by things like fatigue and cognitive overload, and the brain reverts to type 1 processing to conserve cognitive energy. Figure 1.8 illustrates some of the internal and external factors that affect human judgement and decision-making.

Various experiments demonstrate that we focus our attention to filter out distractions. This is advantageous in many situations, but in focusing on what we are trying to see we may not notice the unexpected. In a team context, what is obvious to one person may be completely missed by someone else. Safe and effective team communication therefore requires us never to assume, and to verbalise things, even though they may seem obvious.

---

**Reducing errors in clinical decision-making**

Knowledge and experience do not eliminate errors. Instead, there are a number of ways in which we can act to reduce errors in clinical decision-making. Examples are:

- adopting ‘cognitive debiasing strategies’
- using clinical prediction rules and other decision aids
- engaging in effective team communication.

**Cognitive debiasing strategies**

There are some simple and established techniques that can be used to avoid cognitive biases and errors in clinical decision-making.

**History and physical examination**

Taking a history and performing a physical examination may seem obvious, but these are sometimes carried out inadequately. This is the ‘unpacking principle’: failure to unpack all the available information means things can be missed and lead to error.

**Problem lists and differential diagnosis**

Once all the available data from history, physical examination and (sometimes) initial test results are available, these need to be synthesised into a problem list. The ability to identify key clinical data and create a problem list is a key step in clinical reasoning. Some problems (e.g. low serum potassium) require action but not necessarily a differential diagnosis. Other problems (e.g. vomiting) require a differential diagnosis. The process of generating a problem list ensures nothing is missed. The process of generating a differential diagnosis works against anchoring on a particular diagnosis too early, thereby avoiding search satisficing and premature closure (see Fig. 1.7).

**Mnemonics and checklists**

These are used frequently in medicine in order to reduce reliance on fallible human memory. ABCDE (airway, breathing, circulation, disability, exposure/examination) is probably the most successful checklist in medicine, used during the assessment and treatment of critically ill patients (ABCDE is sometimes prefixed with ‘C’ for ‘control of any obvious problem’; see p. 188). Checklists ensure that important issues have been considered and completed, especially under conditions of complexity, stress or fatigue.

**Red flags and ROWS (‘rule out worst case scenario’)**

These are strategies that force doctors to consider serious diseases that can present with common symptoms. Red flags in back pain are listed in Box 24.19 (p. 996). Considering and investigating for possible pulmonary embolism in patients who

---

**Fig. 1.8** Factors that affect our judgement and decision-making. Type 1 thinking = fast, intuitive, subconscious, low-effort.
present with pleuritic chest pain and breathlessness is a common example of ruling out a worst-case scenario, as pulmonary embolism can be fatal if missed. Red flags and ROWS help to avoid cognitive biases such as the ‘framing effect’ and ‘premature closure’.

Newer strategies to avoid cognitive biases and errors in decision-making are emerging. These involve explicit training in clinical reasoning and human factors. In theory, if doctors are aware of the science of human thinking and decision-making, then they are more able to think about their thinking, understand situations in which their decision-making may be affected, and take steps to mitigate this.

**Using clinical prediction rules and other decision aids**

A clinical prediction rule is a statistical model of the diagnostic process. When clinical prediction rules are matched against the opinion of experts, the model usually outperforms the experts, because it is applied consistently in each case. However, it is important that clinical prediction rules are used correctly – that is, applied to the patient population that was used to create the rule. Clinical prediction rules force a scientific assessment of the patient’s symptoms, signs and other data to develop a numerical probability of a disease or an outcome. They help clinicians to estimate probability more accurately.

A good example of a clinical prediction rule to estimate pre-test probability is the Wells score in suspected deep vein thrombosis (see *Box 10.15*, p. 187). Other commonly used clinical prediction rules predict outcomes and therefore guide the management plan. These include the GRACE score in acute coronary syndromes (see *Fig. 16.62*, p. 494) and the CURB-65 score in community-acquired pneumonia (see *Fig. 17.32*, p. 583).

**Effective team communication**

Effective team communication and proper handovers are vital for safe clinical care. The SBAR system of communicating has been recommended by the UK’s Patient Safety First campaign. It is a structured way to communicate about a patient with another health-care professional (e.g. during handover or when making a referral) and increases the amount of relevant information being communicated in a shorter time. It is illustrated in *Box 1.7*.

In increasingly complex health-care systems, patients are looked after by a wide variety of professionals, each of whom has access to important information required to make clinical decisions. Strict hierarchies are hazardous to patient safety if certain members of the team are not able to speak up.

**Patient-centred evidence-based medicine and shared decision-making**

‘Patient-centred evidence-based medicine’ refers to the application of best-available research evidence while taking individual patient factors into account; these include both clinical and non-clinical factors (e.g. the patient’s social circumstances, values and wishes). For example, a 95-year-old man with dementia and a recent gastrointestinal bleed is admitted with an inferior myocardial infarction. He is clinically well. Should he be treated with dual antiplatelet therapy and low-molecular-weight heparin as recommended in clinical guidelines?

As this chapter has described, clinicians frequently deal with uncertainty/probability. Clinicians need to be able to explain risks and benefits of treatment in an accurate and understandable way. Providing the relevant statistics is seldom sufficient to guide decision-making because a patient’s perception of risk may be influenced by irrational factors as well as individual values.

Research evidence provides statistics but these can be confusing. Terms such as ‘common’ and ‘rare’ are nebulous. Whenever possible, clinicians should quote numerical information using consistent denominators (e.g. ‘90 out of 100 patients who have this operation feel much better, 1 will die during the operation and 2 will suffer a stroke’). Visual aids can be used to present complex statistical information (Fig. 1.9).

How uncertainty is conveyed to patients is important. Many studies demonstrate a correlation between effective clinician–patient communication and improved health outcomes. If patients feel they have been listened to and understand the problem and proposed treatment plan, they are more likely to follow the plan and less likely to re-attend.

**Clinical decision-making: putting it all together**

The following is a practical example that brings together many of the concepts outlined in this chapter:

A 25-year-old woman presents with right-sided pleuritic chest pain and breathlessness. She reports that she had an upper
respiratory tract infection a week ago and was almost back to normal when the symptoms started. The patient has no past medical history and no family history, and her only medication is the combined oral contraceptive pill. On examination, her vital signs are normal (respiratory rate 19 breaths/min, oxygen saturations 98% on air, blood pressure 115/60 mmHg, heart rate 90 beats/min, temperature 37.5°C) and the physical examination is also normal. You have been asked to assess her for the possibility of a pulmonary embolism.

(More information on pulmonary embolism can be found on page 619.)

### Evidence-based history and examination

Information from the history and physical examination is vital in deciding whether this could be a pulmonary embolism. Pleurisy and breathlessness are common presenting features of this disease but are also common presenting features in other diseases. There is nothing in the history to suggest an alternative diagnosis (e.g. high fever, productive cough, recent chest trauma). The patient’s vital signs are normal, as is the physical examination. However, the only feature in the history and examination that has a negative likelihood ratio in the diagnosis of pulmonary embolism is a heart rate of less than 90 beats/min. In other words, the normal physical examination findings (including normal oxygen saturations) carry very little diagnostic weight.

### Deciding pre-test probability

The prevalence of pulmonary embolism in 25-year-old women is low. We anchor on this prevalence and then adjust for individual patient factors. This patient has no major risk factors for pulmonary embolism. To assist our estimate of pre-test probability, we could use a clinical prediction rule: in this case, the modified Wells score for pulmonary embolism, which would give a score of 3 (low probability – answering yes only to the criterion ‘PE is the number one diagnosis, an alternative is less likely’).

### Interpreting test results

Imagine the patient went on to have a normal chest X-ray and blood results, apart from a raised D-dimer of 900 (normal <500 ng/mL). A normal chest X-ray is a common finding in pulmonary embolism. Several studies have shown that the D-dimer assay has at least 95% sensitivity in acute pulmonary embolism but it has a low specificity. A very sensitive test will detect most disease but generate abnormal findings in healthy people. On the other hand, a negative result virtually, but not completely, excludes the disease. It is important at this point to realise that a raised D-dimer result does not mean this patient has a pulmonary embolism; it just means that we have not been able to exclude it. Since pulmonary embolism is a potentially fatal condition we need to rule out the worst-case scenario (ROWS), and the next step is therefore to arrange further imaging. What kind of imaging depends on individual patient characteristics and what is available.

### Treatment threshold

The treatment threshold combines factors such as the risks of the test, and the risks versus benefits of treatment. A CT pulmonary angiogram (CTPA) could be requested for this patient, although in some circumstances ventilation–perfusion single-photon emission computed tomography (V/Q SPECT, p. 623) may be a more suitable alternative. However, what if the scan cannot be performed until the next day? Because pulmonary embolism is potentially fatal and the risks of treatment in this case are low, the patient should be started on treatment while awaiting the scan.

### Post-test probability

The patient’s scan result is subsequently reported as ‘no pulmonary embolism’. Combined with the low pre-test probability, this scan result reliably excludes pulmonary embolism.

### Cognitive biases

Imagine during this case that the patient had been handed over to you as ‘nothing wrong – probably a pulled muscle’. Cognitive biases (subconscious tendencies to respond in a certain way) would come into play, such as the ‘framing effect’, ‘confirmation bias’ and ‘search satisficing’. The normal clinical examination might confirm the diagnosis of musculoskeletal pain in your mind, despite the examination being entirely consistent with pulmonary embolism and despite the lack of history and examination findings (e.g. chest wall tenderness) to support the diagnosis of musculoskeletal chest pain.

### Human factors

Imagine that, after you have seen the patient, a nurse hands you some blood forms and asks you what tests you would like to request on ‘this lady’. You request blood tests including a D-dimer on the wrong patient. Luckily, this error is intercepted.

### Reducing cognitive error

The diagnosis of pulmonary embolism can be difficult. Clinical prediction rules (e.g. modified Wells score), guidelines (e.g. from the UK’s National Institute for Health and Care Excellence, or NICE) and decision aids (e.g. simplified pulmonary embolism severity index, or PESI) are frequently used in combination with the doctor’s opinion, derived from information gathered in the history and physical examination.
The distinctive mark of this easy puzzle is that it evokes an answer that is intuitive, appealing – and wrong. Do the math, and you will see.’ The correct answer is 5p.

Answers to problems

Harvard problem (p. 5)
Almost half of doctors surveyed said 95%, but they neglected to take prevalence into account. If 1000 people are tested, there will be 51 positive results: 50 false positives and 1 true positive. The chance that a person found to have a positive result actually has the disease is 1/51 or 2%.

Bat and ball problem (p. 6)
This puzzle is from the book, Thinking, Fast and Slow, by Nobel laureate Daniel Kahneman (see ‘Further information’). He writes, ‘A number came to your mind. The number, of course, is 10p.'

Prescribing medicines is the major tool used by doctors to restore or preserve the health of patients. Medicines contain drugs (the specific chemical substances with pharmacological effects), either alone or in combination with additional drugs, in a formulation mixed with other ingredients. The beneficial effects of medicines must be weighed against their cost and potential adverse drug reactions and interactions. The latter two factors are sometimes caused by injudicious prescribing decisions and by prescribing errors. The modern prescriber must meet the challenges posed by the increasing number of drugs and formulations available and of indications for prescribing them, and the greater complexity of treatment regimens followed by individual patients (‘polypharmacy’, a particular challenge in the ageing population). The purpose of this chapter is to elaborate on the principles and practice that underpin good prescribing (Box 2.1).

### 2.1 Steps in good prescribing

- Make a diagnosis
- Consider factors that might influence the patient’s response to therapy (age, concomitant drug therapy, renal and liver function etc.)
- Establish the therapeutic goal*
- Choose the therapeutic approach*
- Choose the drug and its formulation (the ‘medicine’)
- Choose the dose, route and frequency
- Choose the duration of therapy
- Write an unambiguous prescription (or ‘medication order’)
- Inform the patient about the treatment and its likely effects
- Monitor treatment effects, both beneficial and harmful
- Review/alter the prescription

*These steps in particular take the patient’s views into consideration to establish a therapeutic partnership (shared decision-making to achieve ‘concordance’).

## Principles of clinical pharmacology

Prescribers need to understand what the drug does to the body (pharmacodynamics) and what the body does to the drug (pharmacokinetics) (Fig. 2.1). Although this chapter is focused on the most common drugs, which are synthetic small molecules, the same principles apply to the increasingly numerous ‘biological’ therapies (sometimes abbreviated to ‘biologics’) now in use, which include peptides, proteins, enzymes and monoclonal antibodies (see Box 4.2, p. 65).

### Pharmacodynamics

#### Drug targets and mechanisms of action

Modern drugs are usually discovered by screening compounds for activity either to stimulate or to block the function of a specific molecular target, which is predicted to have a beneficial effect in a particular disease (Box 2.2). Other drugs have useful but less selective chemical properties, such as chelators (e.g. for treatment of iron or copper overload), osmotic agents (used as diuretics in cerebral oedema) or general anaesthetics (that alter the biophysical properties of lipid membranes). The following characteristics of the interaction of drugs with receptors illustrate some of the important determinants of the effects of drugs:

- **Affinity** describes the propensity for a drug to bind to a receptor and is related to the ‘molecular fit’ and the strength of the chemical bond. Some drug–receptor interactions are irreversible, either because the affinity is so strong or because the drug modifies the structure of its molecular target.
- **Selectivity** describes the propensity for a drug to bind to one target rather than another. Selectivity is a relative term, not to be confused with absolute specificity. It is common for drugs targeted at a particular subtype of receptor to exhibit some effect at other subtypes. For example, β-adrenoceptors can be subtyped on the basis of their responsiveness to the endogenous agonist noradrenaline (norepinephrine): the concentration of noradrenaline required to cause bronchodilatation (via β₂-adrenoceptors) is ten times higher than that required to cause tachycardia (via β₁-adrenoceptors). ‘Cardioselective’ β-blockers have anti-anginal effects on the heart (β₁) but may still cause bronchospasm in the lung (β₂) and are contraindicated for asthmatic patients.
- **Agonists** bind to a receptor to produce a conformational change that is coupled to a biological response. As agonist concentration increases, so does the proportion of receptors occupied, and hence the biological effect. Partial agonists activate the receptor but cannot produce a maximal signalling effect equivalent to that of a full agonist, even when all available receptors are occupied.
- **Antagonists** bind to a receptor but do not produce the conformational change that initiates an intracellular signal. A competitive antagonist competes with endogenous ligands to occupy receptor-binding sites, with the resulting antagonism depending on the relative affinities and concentrations of drug and ligand. Non-competitive antagonists inhibit the effect of an agonist by mechanisms other than direct competition for receptor binding with the agonist (e.g. by affecting post-receptor signalling).

#### Dose–response relationships

Plotting the logarithm of drug dose against drug response typically produces a sigmoidal dose–response curve (Fig. 2.2). Progressive increases in drug dose (which, for most drugs, is proportional to the plasma drug concentration) produce increasing...
Fig. 2.2 Dose–response curve. The green curve represents the beneficial effect of the drug. The maximum response on the curve is the E_max and the dose (or concentration) producing half this value (E_max/2) is the ED_{50} or EC_{50}. The red curve illustrates the dose–response relationship for the most important adverse effect of this drug. This occurs at much higher doses; the ratio between the ED_{50} for the adverse effect and that for the beneficial effect is the ‘therapeutic index’, which indicates how much margin there is for prescribers when choosing a dose that will provide beneficial effects without also causing this adverse effect. Adverse effects that occur at doses above the therapeutic range are normally called ‘toxic effects’, while those occurring within the therapeutic range are ‘side-effects’ and those below it are ‘hyper-susceptibility effects’.

(ACE = angiotensin-converting enzyme; AMP = adenosine monophosphate; ATPase = adenosine triphosphatase; GABA = γ-aminobutyric acid; GMP = guanosine monophosphate; PPAR = peroxisome proliferator-activated receptor)
response but only within a relatively narrow range of dose; further increases in dose beyond this range produce little extra effect. The following characteristics of the drug response are useful in comparing different drugs:

- **Efficacy** describes the extent to which a drug can produce a target-specific response when all available receptors or binding sites are occupied (i.e. $E_{\text{max}}$ on the dose–response curve). A full agonist can produce the maximum response of which the receptor is capable, while a partial agonist at the same receptor will have lower efficacy. Therapeutic efficacy describes the effect of the drug on a desired biological endpoint and can be used to compare drugs that act via different pharmacological mechanisms (e.g. loop diuretics induce a greater diuresis than thiazide diuretics and therefore have greater therapeutic efficacy).
- **Potency** describes the amount of drug required for a given response. More potent drugs produce biological effects at lower doses, so they have a lower $ED_{50}$. A less potent drug can still have an equivalent efficacy if it is given in higher doses.

The dose–response relationship varies between patients because of variations in the many determinants of pharmacokinetics and pharmacodynamics. In clinical practice, the prescriber is unable to construct a dose–response curve for each individual patient. Therefore, most drugs are licensed for use within a recommended range of doses that is expected to reach close to the top of the dose–response curve for most patients. However, it is sometimes possible to achieve the desired therapeutic efficacy at doses towards the lower end of, or even below, the recommended range.

**Therapeutic index**

The adverse effects of drugs are often dose-related in a similar way to the beneficial effects, although the dose–response curve for these adverse effects is normally shifted to the right (Fig. 2.2). The ratio of the $ED_{50}$ for therapeutic efficacy and for a major adverse effect is known as the ‘therapeutic index’. In reality, drugs have multiple potential adverse effects, but the concept of therapeutic index is usually based on adverse effects that might require dose reduction or discontinuation. For most drugs, the therapeutic index is greater than 100 but there are some notable exceptions with therapeutic indices of less than 10 (e.g. digoxin, warfarin, insulin, phenytoin, opioids). The doses of such drugs have to be titrated carefully for individual patients to maximise benefits but avoid adverse effects.

**Desensitisation and withdrawal effects**

Desensitisation refers to the common situation in which the biological response to a drug diminishes when it is given continuously or repeatedly. It may be possible to restore the response by increasing the dose of the drug but, in some cases, the tissues may become completely refractory to its effect.

- **Tachyphylaxis** describes desensitisation that occurs very rapidly, sometimes with the initial dose. This rapid loss of response implies depletion of chemicals that may be necessary for the pharmacological actions of the drug (e.g. a stored neurotransmitter released from a nerve terminal) or receptor phosphorylation.
- **Tolerance** describes a more gradual loss of response to a drug that occurs over days or weeks. This slower change implies changes in receptor numbers or the development of counter-regulatory physiological changes that offset the actions of the drug (e.g. accumulation of salt and water in response to vasodilator therapy).
- **Drug resistance** is a term normally reserved for describing the loss of effectiveness of an antimicrobial (p. 116) or cancer chemotherapy drug.
- In addition to these pharmacodynamic causes of desensitisation, reduced response may be the consequence of lower plasma and tissue drug concentrations as a result of altered pharmacokinetics (see below).

When drugs induce chemical, hormonal and physiological changes that offset their actions, discontinuation may allow these changes to cause ‘rebound’ withdrawal effects (Box 2.3).

Pharmacokinetics

Understanding “what the body does to the drug” (Fig. 2.3) is extremely important for prescribers because this forms the basis on which the optimal route of administration and dose regimen are chosen and explains the majority of inter-individual variation in the response to drug therapy.

**Drug absorption and routes of administration**

Absorption is the process by which drug molecules gain access to the blood stream. The rate and extent of drug absorption depend on the route of administration (Fig. 2.3).

**Enteral administration**

These routes involve administration via the gastrointestinal tract:

- **Oral**. This is the most common route of administration because it is simple, convenient and readily used by patients to self-administer their medicines. Absorption after an oral dose is a complex process that depends on the drug being swallowed, surviving exposure to gastric acid, avoiding unacceptable food binding, being absorbed across the small bowel mucosa into the portal venous system, and surviving metabolism by gut wall or liver enzymes (“first-pass metabolism”). As a consequence, absorption is frequently incomplete following oral administration. The term ‘bioavailability’ describes the proportion of the dose that reaches the systemic circulation intact.

- **Buccal, intranasal and sublingual (SL)**. These routes have the advantage of enabling rapid absorption into the systemic circulation without the uncertainties associated with oral administration (e.g. organic nitrates for angina pectoris, triptans for migraine, opioid analgesics).

- **Rectal (PR)**. The rectal mucosa is occasionally used as a site of drug administration when the oral route is compromised because of nausea and vomiting or unconsciousness (e.g. diazepam in status epilepticus).

**Parenteral administration**

These routes avoid absorption via the gastrointestinal tract and first-pass metabolism in the liver:

- **Intravenous (IV)**. The IV route enables all of a dose to enter the systemic circulation reliably, without any concerns about absorption or first-pass metabolism (i.e. the dose is 100% bioavailable), and rapidly achieve a high plasma concentration. It is ideal for very ill patients when a rapid certain effect is critical to outcome (e.g. benzathine benzylpenicillin for meningococcal meningitis).

- **Intramuscular (IM)**. IM administration is easier to achieve than the IV route (e.g. adrenaline (epinephrine) for acute anaphylaxis) but absorption is less predictable and depends on muscle blood flow.

- **Subcutaneous (SC)**. The SC route is ideal for drugs that have to be administered parenterally because of low oral bioavailability, are absorbed well from subcutaneous fat, and might ideally be injected by patients themselves (e.g. insulin, heparin).

- **Transdermal**. A transdermal patch can enable a drug to be absorbed through the skin and into the circulation (e.g. oestrogens, nicotine, nitrates).

**Other routes of administration**

- **Topical** application of a drug involves direct administration to the site of action (e.g. skin, eye, ear). This has the advantage of achieving sufficient concentration at this site while minimising systemic exposure and the risk of adverse effects elsewhere.

- **Inhaled (INH)** administration allows drugs to be delivered directly to a target in the respiratory tree, usually the small airways (e.g. salbutamol, beclometasone). However, a significant proportion of the inhaled dose may be absorbed from the lung or is swallowed and can reach the systemic circulation. The most common mode of delivery is the metered-dose inhaler but its success depends on some degree of manual dexterity and timing (see Fig. 17.23, p. 571). Patients who find these difficult may use a ‘spacer’ device to improve drug delivery. A special mode

---

**Fig. 2.3 Pharmacokinetics summary.** Most drugs are taken orally, are absorbed from the intestinal lumen and enter the portal venous system to be conveyed to the liver, where they may be subject to first-pass metabolism and/or excretion in bile. Active drugs then enter the systemic circulation, from which they may diffuse (or sometimes be actively transported) in and out of the interstitial and intracellular fluid compartments. Drug that remains in circulating plasma is subject to liver metabolism and renal excretion. Drugs excreted in bile may be reabsorbed, creating an enterohepatic circulation. First-pass metabolism in the liver is avoided if drugs are administered via the buccal or rectal mucosa, or parenterally (e.g. by intravenous injection).
of inhaled delivery is via a nebulised solution created by using pressurised oxygen or air to break up solutions and suspensions into small aerosol droplets that can be directly inhaled from the mouthpiece of the device.

## Drug distribution

Distribution is the process by which drug molecules transfer into and out of the bloodstream. This is influenced by the drug’s molecular size and lipid solubility, the extent to which it binds to proteins in plasma, its susceptibility to drug transporters expressed on cell surfaces, and its binding to its molecular target and to other cellular proteins (which can be irreversible). Most drugs diffuse passively across capillary walls down a concentration gradient into the interstitial fluid until the concentration of free drug molecules in the interstitial fluid is equal to that in the plasma. As drug molecules in the blood are removed by metabolism or excretion, the plasma concentration falls, drug molecules diffuse back from the tissue compartment into the blood and eventually all will be eliminated. Note that this reverse movement of drug away from the tissues will be prevented if further drug doses are administered and absorbed into the plasma.

### Volume of distribution

The apparent volume of distribution \((V_d)\) is the volume into which a drug appears to have distributed following intravenous injection. It is calculated from the equation

\[
V_d = \frac{D}{C_0}
\]

where \(D\) is the amount of drug given and \(C_0\) is the initial plasma concentration (Fig. 2.4A). Drugs that are highly bound to plasma proteins may have a \(V_d\) below 10 L (e.g. warfarin, aspirin), while those that diffuse into the interstitial fluid but do not enter cells because they have low lipid solubility may have a \(V_d\) between 10 and 30 L (e.g. gentamicin, amoxicillin). It is an ‘apparent’ volume because those drugs that are lipid-soluble and highly tissue-bound may have a \(V_d\) of greater than 100 L (e.g. digoxin, amitriptyline). Drugs with a larger \(V_d\) have longer half-lives (see below), take longer to reach steady state on repeated administration and are eliminated more slowly from the body following discontinuation.

## Drug elimination

### Drug metabolism

Metabolism is the process by which drugs are chemically altered from a lipid-soluble form suitable for absorption and distribution to a more water-soluble form that is necessary for excretion. Some drugs, known as ‘prodrugs’, are inactive in the form in which they are administered but are converted to an active metabolite in vivo.

Phase I metabolism involves oxidation, reduction or hydrolysis to make drug molecules suitable for phase II reactions or for excretion. Oxidation is by far the most common form of phase I reaction and chiefly involves members of the cytochrome P450 family of membrane-bound enzymes in the endoplasmic reticulum of hepatocytes.

Phase II metabolism involves combining phase I metabolites with an endogenous substrate to form an inactive conjugate that is much more water-soluble. Reactions include glucuronidation, sulphation, acetylation, methylation and conjugation with glutathione. This is necessary to enable renal excretion, because lipid-soluble metabolites will simply diffuse back into the body after glomerular filtration (p. 349).

### Drug excretion

Excretion is the process by which drugs and their metabolites are removed from the body.

Renal excretion is the usual route of elimination for drugs or their metabolites that are of low molecular weight and sufficiently water-soluble to avoid reabsorption from the renal tubule. Drugs bound to plasma proteins are not filtered by the glomeruli. The pH of the urine is more acidic than that of plasma, so that some drugs (e.g. salicylates) become un-ionised and tend to
be reabsorbed. Alkalination of the urine can hasten excretion (e.g. after a salicylate overdose; p. 138). For some drugs, active secretion into the proximal tubule lumen, rather than glomerular filtration, is the predominant mechanism of excretion (e.g. methotrexate, penicillin).

Faecal excretion is the predominant route of elimination for drugs with high molecular weight, including those that are excreted in the bile after conjugation with glucuronide in the liver, and any drugs that are not absorbed after enteral administration. Molecules of drug or metabolite that are excreted in the bile enter the small intestine, where they may, if they are sufficiently lipid-soluble, be reabsorbed through the gut wall and return to the liver via the portal vein (see Fig. 2.3). This recycling between the liver, bile, gut and portal vein is known as ‘enterohepatic circulation’ and can significantly prolong the residence of drugs in the body.

**Elimination kinetics**

The net removal of drug from the circulation results from a combination of drug metabolism and excretion, and is usually described as ‘clearance’, i.e. the volume of plasma that is completely cleared of drug per unit time.

For most drugs, elimination is a high-capacity process that does not become saturated, even at high dosage. The rate of elimination is therefore directly proportional to the drug concentration because of the ‘law of mass action’, whereby higher drug concentrations will drive faster metabolic reactions and support higher renal filtration rates. This results in ‘first-order’ kinetics, when a constant fraction of the drug remaining in the circulation is eliminated in a given time and the decline in concentration over time is exponential (Fig. 2.4A). This elimination can be described by the drug’s half-life ($t_{1/2}$), i.e. the time taken for the plasma drug concentration to halve, which remains constant throughout the period of drug elimination. The significance of this phenomenon for prescribers is that the effect of increasing doses on plasma concentration is predictable – a doubled dose leads to a doubled concentration at all time points.

For a few drugs in common use (e.g. phenytoin, alcohol), elimination capacity is exceeded (saturated) within the usual dose range. This is called ‘zero-order’ kinetics. Its significance for prescribers is that, if the rate of administration exceeds the maximum rate of elimination, the drug will accumulate progressively, leading to serious toxicity.

**Repeated dose regimens**

The goal of therapy is usually to maintain drug concentrations within the therapeutic range (see Fig. 2.2) over several days (e.g. antibiotics) or even for months or years (e.g. antihypertensives, lipid-lowering drugs, thyroid hormone replacement therapy). This goal is rarely achieved with single doses, so prescribers have to plan a regimen of repeated doses. This involves choosing the size of each individual dose and the frequency of dose administration.

As illustrated in Figure 2.4B, the time taken to reach drug concentrations within the therapeutic range depends on the half-life of the drug. Typically, with doses administered regularly, it takes approximately 5 half-lives to reach a ‘steady state’ in which the rate of drug elimination is equal to the rate of drug administration. This applies when starting new drugs and when adjusting doses of current drugs. With appropriate dose selection, steady-state drug concentrations will be maintained within the therapeutic range. This is important for prescribers because it means that the effects of a new prescription, or dose titration, for a drug with a long half-life (e.g. digoxin – 36 hours) may not be known for a few days. In contrast, drugs with a very short half-life (e.g. dobutamine – 2 minutes) have to be given continuously by infusion but reach a new steady state within minutes.

For drugs with a long half-life, if it is unacceptable to wait for 5 half-lives until concentrations within the therapeutic range are achieved, then an initial ‘loading dose’ can be given that is much larger than the maintenance dose and equivalent to the amount of drug required in the body at steady state. This achieves a peak plasma concentration close to the plateau concentration, which can then be maintained by successive maintenance doses.

‘Steady state’ actually involves fluctuations in drug concentrations, with peaks just after administration followed by troughs just prior to the next administration. The manufacturers of medicines recommend dosing regimens that predict that, for most patients, these oscillations result in troughs within the therapeutic range and peaks that are not high enough to cause adverse effects. The optimal dose interval is a compromise between convenience for the patient and a constant level of drug exposure. More frequent administration (e.g. 25 mg 4 times daily) achieves a smoother plasma concentration profile than 100 mg once daily but is much more difficult for patients to sustain. A solution to this need for compromise in dosing frequency for drugs with half-lives of less than 24 hours is the use of ‘modified-release’ formulations. These allow drugs to be absorbed more slowly from the gastrointestinal tract and reduce the oscillation in plasma drug concentration profile, which is especially important for drugs with a low therapeutic index (e.g. levodopa).

**Inter-individual variation in drug responses**

Prescribers have numerous sources of guidance about how to use drugs appropriately (e.g. dose, route, frequency, duration) for many conditions. However, this advice is based on average dose–response data derived from observations in many individuals. When applying this information to an individual patient, prescribers must take account of inter-individual variability in response. Some of this variability is predictable and good prescribers are able to anticipate it and adjust their prescriptions accordingly to maximise the chances of benefit and minimise harm. Inter-individual variation in responses also mandates that effects of treatment should be monitored (p. 34).

Some inter-individual variation in drug response is accounted for by differences in pharmacodynamics. For example, the beneficial natriuresis produced by the loop diuretic furosemide is often significantly reduced at a given dose in patients with renal impairment, while delirium caused by opioid analgesics is more likely in the elderly. Differences in pharmacokinetics more commonly account for different drug responses, however. Examples of factors influencing the absorption, metabolism and excretion of drugs are shown in Box 2.4.

It is hoped that a significant proportion of the inter-individual variation in drug responses can be explained by studying genetic differences in single genes (‘pharmacogenetics’; Box 2.5) or the effects of multiple gene variants (‘pharmacogenomics’). The aim is to identify those patients most likely to benefit from specific treatments and those most susceptible to adverse effects. In this way, it may be possible to select drugs and dose regimens for individual patients to maximise the benefit-to-hazard ratio (‘personalised medicine’).
### 2.4 Patient-specific factors that influence pharmacokinetics

<table>
<thead>
<tr>
<th>Factor</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug metabolism</td>
<td>Drug metabolism is low in the fetus and newborn, may be enhanced in young children, and becomes less effective with age.</td>
</tr>
<tr>
<td>Drug excretion</td>
<td>Drug excretion falls with the age-related decline in renal function.</td>
</tr>
<tr>
<td>Sex</td>
<td>Women have a greater proportion of body fat than men, increasing the volume of distribution and half-life of lipid-soluble drugs.</td>
</tr>
<tr>
<td>Body weight</td>
<td>Obesity increases volume of distribution and half-life of lipid-soluble drugs.</td>
</tr>
<tr>
<td></td>
<td>Patients with higher lean body mass have larger body compartments into which drugs are distributed and may require higher doses.</td>
</tr>
<tr>
<td>Liver function</td>
<td>Metabolism of most drugs depends on several cytochrome P450 enzymes that are impaired in patients with advanced liver disease.</td>
</tr>
<tr>
<td></td>
<td>Hypoalbuminaemia influences the distribution of drugs that are highly protein-bound.</td>
</tr>
<tr>
<td>Kidney function</td>
<td>Renal disease and the decline in renal function with ageing may lead to drug accumulation.</td>
</tr>
<tr>
<td>Gastrointestinal function</td>
<td>Small intestinal absorption of oral drugs may be delayed by reduced gastric motility.</td>
</tr>
<tr>
<td></td>
<td>Absorptive capacity of the intestinal mucosa may be reduced in disease (e.g. Crohn’s or coeliac disease) or after surgical resection.</td>
</tr>
<tr>
<td>Food</td>
<td>Food in the stomach delays gastric emptying and reduces the rate (but not usually the extent) of drug absorption.</td>
</tr>
<tr>
<td></td>
<td>Some food constituents bind to certain drugs and prevent their absorption.</td>
</tr>
<tr>

**Adverse outcomes of drug therapy**

The decision to prescribe a drug always involves a judgement of the balance between therapeutic benefits and risk of an adverse outcome. Both prescribers and patients tend to be more focused on the former but a truly informed decision requires consideration of both.

**Adverse drug reactions**

Some important definitions for the adverse effects of drugs are:

- **Adverse event.** A harmful event that occurs while a patient is taking a drug, irrespective of whether the drug is suspected of being the cause.

- **Adverse drug reaction (ADR).** An unwanted or harmful reaction that is experienced following the administration of a drug or combination of drugs under normal conditions of use and is suspected to be related to the drug. An ADR will usually require the drug to be discontinued or the dose reduced.

- **Side-effect.** Any effect caused by a drug other than the intended therapeutic effect, whether beneficial, neutral or harmful. The term ‘side-effect’ is often used interchangeably with ‘ADR’, although the former usually implies an ADR that occurs during exposure to normal therapeutic drug concentrations (e.g. vasodilator-induced ankle oedema).

- **Hypersensitivity reaction.** An ADR that occurs as a result of an immunological reaction and often at exposure to subtherapeutic drug concentrations. Some of these reactions are immediate and result from the interaction of drug antigens with immunoglobulin E (IgE) on mast cells and basophils, which causes a release of vasoactive biomolecules (e.g. penicillin-related anaphylaxis). ‘Anaphylactoid’ reactions present similarly but occur through a direct non-immune-mediated release of the same mediators or result from direct complement activation (p. 75). Hypersensitivity reactions may occur via other mechanisms such as antibody-dependent (IgM or IgG), immune complex-mediated or cell-mediated pathways.

- **Drug toxicity.** Adverse effects of a drug that occur because the dose or plasma concentration has risen above the therapeutic range, either unintentionally or intentionally (drug overdose; see Fig. 2.2 and p. 137).

- **Drug abuse.** The misuse of recreational or therapeutic drugs that may lead to addiction or dependence, serious physiological injury (such as liver damage), psychological harm (abnormal behaviour patterns, hallucinations, memory loss) or death (p. 1184).

**Prevalence of ADRs**

ADRs are a common cause of illness, accounting in the UK for approximately 3% of consultations in primary care and 7% of emergency admissions to hospital, and affecting around 15% of hospital inpatients. Many ‘disease’ presentations are eventually attributed to ADRs, emphasising the importance of always taking a careful drug history (Box 2.6). Factors accounting for the rising prevalence of ADRs are the increasing age of patients, polypharmacy (higher risk of drug interactions), increasing availability of over-the-counter medicines, increasing use of herbal or traditional medicines, and the increase in medicines available via the Internet that can be purchased without a prescription from a health-care professional. Risk factors for ADRs are shown in Box 2.7.

---

**2.6 How to take a drug history**

**Information from the patient (or carer)**

Use language that patients will understand (e.g. ‘medicines’ rather than ‘drugs’, which may be mistaken for drugs of abuse) while gathering the following information:

- Current prescribed drugs, including formulations (e.g. modified-release tablets), doses, routes of administration, frequency and timing, duration of treatment
- Other medications that are often forgotten (e.g. contraceptives, over-the-counter drugs, herbal remedies, vitamins)
- Drugs that have been taken in the recent past and reasons for stopping them
- Previous drug hypersensitivity reactions, their nature and time course (e.g. rash, anaphylaxis)
- Previous ADRs, their nature and time course (e.g. ankle oedema with amlodipine)
- Adherence to therapy (e.g. ‘Are you taking your medication regularly?’)

**Information from GP medical records and/or pharmacist**

- Up-to-date list of medications
- Previous ADRs
- Last order dates for each medication

**Inspection of medicines**

- Drugs and their containers (e.g. blister packs, bottles, vials) should be inspected for name, dosage, and the number of dosage forms taken since dispensed

(ADR = adverse drug reaction)

---

**2.7 Risk factors for adverse drug reactions**

**Patient factors**

- Elderly age (e.g. low physiological reserve)
- Gender (e.g. ACE inhibitor-induced cough in women)
- Polypharmacy (e.g. drug interactions)
- Genetic predisposition (see Box 2.5)
- Hypersensitivity/allergy (e.g. β-lactam antibiotics)
- Diseases altering pharmacokinetics (e.g. hepatic or renal impairment) or pharmacodynamic responses (e.g. bladder instability)
- Adherence problems (e.g. cognitive impairment)

**Drug factors**

- Steep dose–response curve (e.g. insulin)
- Low therapeutic index (e.g. digoxin, cytotoxic drugs)

**Prescriber factors**

- Inadequate understanding of principles of clinical pharmacology
- Inadequate knowledge of the patient
- Inadequate knowledge of the prescribed drug
- Inadequate instructions and warnings provided to patients
- Inadequate monitoring arrangements planned

(ACE = angiotensin-converting enzyme)
ADRs are important because they reduce quality of life for patients, reduce adherence to and therefore efficacy of beneficial treatments, cause diagnostic confusion, undermine the confidence of patients in their health-care professional(s) and consume health-care resources.

Retrospective analysis of ADRs has shown that more than half could have been avoided if the prescriber had taken more care in anticipating the potential hazards of drug therapy. For example, non-steroidal anti-inflammatory drug (NSAID) use accounts for many thousands of emergency admissions, gastrointestinal bleeding episodes and a significant number of deaths. In many cases, the patients are at increased risk due to their age, interacting drugs (e.g. aspirin, warfarin) or a past history of peptic ulcer disease. Drugs that commonly cause ADRs are listed in Box 2.8.

Prescribers and their patients ideally want to know the frequency with which ADRs occur for a specific drug. Although this may be well characterised for more common ADRs observed in clinical trials, it is less clear for rarely reported ADRs when the total numbers of reactions and patients exposed are not known. The words used to describe frequency can be misinterpreted by patients but widely accepted meanings include: very common (10% or more), common (1–10%), uncommon (0.1–1%), rare (0.01–0.1%) and very rare (0.01% or less).

**Classification of ADRs**

ADRs have traditionally been classified into two major groups:

- **Type A (‘augmented’) ADRs.** These are predictable from the known pharmacodynamic effects of the drug and are dose-dependent, common (detected early in drug development) and usually mild. Examples include constipation caused by opioids, hypotension caused by antihypertensives and dehydration caused by diuretics.

- **Type B (‘bizarre’) ADRs.** These are not predictable, are not obviously dose-dependent in the therapeutic range, are rare (remaining undiscovered until the drug is marketed) and often severe. Patients who experience type B reactions are generally ‘hyper-susceptible’ because of unpredictable immunological or genetic factors (e.g. anaphylaxis caused by penicillin, peripheral neuropathy caused by isoniazid in poor acetylators).

This simple classification has shortcomings, and a more detailed classification based on dose (see Fig. 2.2), timing and susceptibility (DoTS) is now used by those analysing ADRs in greater depth (Box 2.9). The AB classification can be extended as a reminder of some other types of ADR:

- **Type C (‘chronic/continuous’) ADRs.** These occur only after prolonged continuous exposure to a drug. Examples include osteoporosis caused by glucocorticoids, retinopathy caused by chloroquine, and tardive dyskinesia caused by phenothiazines.

- **Type D (‘delayed’) ADRs.** These are delayed until long after drug exposure, making diagnosis difficult. Examples include malignancies that may emerge after immunosuppressive treatment post-transplantation (e.g. azathioprine, tacrolimus) and vaginal cancer occurring many years after exposure to diethylstilboestrol.

- **Type E (‘end-of-treatment’) ADRs.** These occur after abrupt drug withdrawal (see 2.3).

A teratogen is a drug with the potential to affect the development of the fetus in the first 10 weeks of intrauterine life (e.g. phenytoin, warfarin). The thalidomide disaster in the early 1960s highlighted the risk of teratogenicity and led to mandatory testing of all new drugs. Congenital defects in a live infant or aborted fetus should

(INR = international normalised ratio)
provoke suspicion of an ADR and a careful exploration of drug exposures (including self-medication and herbal remedies).

Detecting ADRs – pharmacovigilance

Type A ADRs become apparent early in the development of a new drug. By the time a new drug is licensed and launched on to a possible worldwide market, however, a relatively small number of patients (just several hundred) may have been exposed to it, meaning that rarer but potentially serious type B ADRs may remain undiscovered. Pharmacovigilance is the process of detecting (‘signal generation’) and evaluating ADRs in order to help prescribers and patients to be better informed about the risks of drug therapy. Drug regulatory agencies may respond to this information by placing restrictions on the licensed indications, reducing the recommended dose range, adding special warnings and precautions for prescribers in the product literature, writing to all health-care professionals or withdrawing the product from the market.

Voluntary reporting systems allow health-care professionals and patients to report suspected ADRs to the regulatory authorities. A good example is the ‘Yellow Card’ scheme that was set up in the UK in response to the thalidomide tragedy. Reports are analysed to assess the likelihood that they represent a true ADR (Box 2.10). Although voluntary reporting is a continuously operating and effective early-warning system for previously unrecognised rare ADRs, its weaknesses include low reporting rates (only 3% of all ADRs and 10% of serious ADRs are ever reported), an inability to quantify risk (because the ratio of ADRs to prescriptions is unknown), and the influence of prescriber awareness on likelihood of reporting (reporting rates rise rapidly following publicity about potential ADRs).

More systematic approaches to collecting information on ADRs include ‘prescription event monitoring’, in which a sample of prescriptions of a particular drug are issued with questionnaires concerning the clinical outcome for their patients, and the collection of population statistics. Many health-care systems routinely collect patient-identifiable data on prescriptions (a surrogate marker of exposure to a drug), health-care events (e.g. hospitalisation, operations, new clinical diagnoses) and other clinical data (e.g. haematology, biochemistry). As these records are linked, with appropriate safeguards for confidentiality and data protection, they are providing a much more powerful mechanism for assessing both the harms and benefits of drugs. All prescribers will inevitably see patients experiencing ADRs caused by prescriptions written by themselves or their colleagues. It is important that these are recognised early. In addition to the features in Box 2.10, features that should raise suspicion of an ADR and the need to respond (by drug withdrawal, dosage reduction or reporting to the regulatory authorities) include:

- concern expressed by a patient that a drug has harmed them
- abnormal clinical measurements (e.g. blood pressure, temperature, pulse, blood glucose and weight) or laboratory results (e.g. abnormal liver or renal function, low haemoglobin or white cell count) while on drug therapy
- new therapy started that could be in response to an ADR (e.g. omeprazole, allopurinol, naloxone)
- the presence of risk factors for ADRs (see Box 2.7).

Drug interactions

A drug interaction has occurred when the administration of one drug increases or decreases the beneficial or adverse responses to another drug. Although the number of potential interacting drug combinations is very large, only a small number are common in clinical practice. Important drug interactions are most likely to occur when the affected drug has a low therapeutic index, steep dose–response curve, high first-pass or saturable metabolism, or a single mechanism of elimination.

Mechanisms of drug interactions

Pharmacodynamic interactions occur when two drugs produce additive, synergistic or antagonistic effects at the same drug target (e.g. receptor, enzyme) or physiological system (e.g. electrolyte excretion, heart rate). These are the most common interactions in clinical practice and some important examples are given in Box 2.11.

Pharmacokinetic interactions occur when the administration of a second drug alters the concentration of the first at its site of action. There are numerous potential mechanisms:

- Absorption interactions. Drugs that either delay (e.g. anticholinergic drugs) or enhance (e.g. prokinetic drugs) gastric emptying influence the rate of rise in plasma concentration of other drugs but not the total amount of drug absorbed. Drugs that bind to form insoluble complexes or chelates (e.g. aluminium-containing antacids binding with ciprofloxacin) can reduce drug absorption.
- Distribution interactions. Co-administration of drugs that compete for protein binding in plasma (e.g. phenytoin and diazepam) can increase the unbound drug concentration, but the effect is usually short-lived due to increased elimination and hence restoration of the pre-interaction equilibrium.

(***SPC* = summary of product characteristics)
consequences of drug–drug interactions by taking a careful
drug history (see Box 2.6) before prescribing additional drugs,
only prescribing for clear indications, and taking special care
when prescribing drugs with a narrow therapeutic index (e.g.
warfarin). When prescribing an interacting drug is unavoidable,
good prescribers will seek further information and anticipate the
potential risk. This will allow them to provide special warnings for
the patient and arrange for monitoring, either of the clinical effects
(e.g. coagulation tests for warfarin) or of plasma concentration
(e.g. digoxin).

**Medication errors**

A medication error is any preventable event that may lead to
inappropriate medication use or patient harm while the medication
is in the control of the health-care professional or patient. Errors
may occur in prescribing, dispensing, preparing solutions,
administration or monitoring. Many ADRs are considered in
retrospect to have been ‘avoidable’ with more care or forethought;
in other words, an adverse event considered by one prescriber
to be an unfortunate ADR might be considered by another to
be a prescribing error.

Medication errors are very common. Several thousand
drug interactions are increasing as patients are prescribed more
medicines (polypharmacy). Prescribers can avoid the adverse

*Pharmaceutical interactions are related to the formulation of the drugs and occur before drug absorption. (ACE = angiotensin-converting enzyme; NSAID = non-steroidal anti-inflammatory drug)
7–9% of hospital prescriptions contain an error, and most are written by junior doctors. Common prescribing errors in hospitals include omission of medicines (especially failure to prescribe regular medicines at the point of admission or discharge, i.e. ‘medicines reconciliation’), dosing errors, unintentional prescribing and poor use of documentation (Box 2.12).

Most prescription errors result from a combination of failures by the individual prescriber and the health-service systems in which they work (Box 2.13). Health-care organisations increasingly encourage reporting of errors within a ‘no-blame culture’ so that they can be subject to ‘root cause analysis’ using human error theory (Fig. 2.5). Prevention is targeted at the factors in Box 2.13, and can be supported by prescribers communicating and cross-checking with colleagues (e.g. when calculating doses adjusted for body weight, or planning appropriate monitoring after drug administration), and by health-care systems providing clinical pharmacist support (e.g. for checking the patient’s previous medications and current prescriptions) and electronic prescribing (which avoids errors due to illegibility or serious dosing mistakes, and may be combined with a clinical decision support system to take account of patient characteristics and drug history, and provide warnings of potential contraindications and drug interactions).
Drug regulation and management

Given the powerful beneficial and potentially adverse effects of drugs, the production and use of medicines are strictly regulated (e.g. by the Food and Drug Administration in the USA, Medicines and Healthcare Products Regulatory Agency in the UK, and Central Drugs Standard Control Organisation in India). Regulators are responsible for licensing medicines, monitoring their safety (pharmacovigilance; p. 23), approving clinical trials, and inspecting and maintaining standards of drug development and manufacture.

In addition, because of the high costs of drugs and their adverse effects, health-care services must prioritise their use in light of the evidence of their benefit and harm, a process referred to as ‘medicines management’.

Drug development and marketing

Naturally occurring products have been used to treat illnesses for thousands of years and some remain in common use today. Examples include morphine from the opium poppy (Papaver somniferum), digitalis from the foxglove (Digitalis purpurea), curare from the bark of a variety of species of South American trees, and quinine from the bark of the Cinchona species. Although plants and animals remain a source of discovery, the majority of new drugs come from drug discovery programmes that aim to identify small-molecule compounds with specific interactions with a molecular target that will induce a predicted biological effect.

The usual pathway for development of these small molecules includes: identifying a plausible molecular target by investigating pathways in disease; screening a large library of compounds for those that interact with the molecular target in vitro; conducting extensive medicinal chemistry to optimise the properties of lead compounds; testing efficacy and toxicity of these compounds in vitro and in animals; and undertaking a clinical development programme (Box 2.14). This process typically takes longer than 10 years and may cost up to US$1 billion. Manufacturers have a defined period of exclusive marketing of the drug while it remains protected by an original patent, typically 10–15 years, during which time they must recoup the costs of developing the drug. Meanwhile, competitor companies will often produce similar ‘me too’ drugs of the same class. Once the drug’s patent has expired, ‘generic’ manufacturers may step in to produce cheaper formulations of the drug. Paradoxically, if a generic drug is produced by only one manufacturer, the price may actually rise, sometimes substantially. Newer ‘biological’ products are based on large molecules (e.g. human recombinant antibodies) derived from complex manufacturing processes involving specific cell lines, molecular cloning and purification processes. After the patent for the originator product expires, other manufacturers may develop similar products (‘biosimilars’) that share similar pharmacological actions but are not completely identical. ‘Biosimilars’ are considered distinct from ‘generic’ medications, as complex biological molecules are more susceptible to differences in manufacturing processes than conventional small-molecule-type pharmaceuticals.

The number of new drugs produced by the pharmaceutical industry has declined in recent years. The traditional approach of targeting membrane-bound receptors and enzymes with small molecules (see Box 2.2) is now giving way to new targets, such as complex second-messenger systems, cytokines, nucleic acids and cellular networks. These require novel therapeutic agents, which present new challenges for ‘translational medicine’, the discipline of converting scientific discoveries into a useful medicine with a well-defined benefit–risk profile (Box 2.15).

| Phase I | Patients (20–80) | These involve initial single-dose, ‘first-into-man’ studies, followed by repeated-dose studies. They aim to establish the basic pharmacokinetic and pharmacodynamic properties, and short-term safety | Duration: 6–12 months |
| Phase II | Patients (100–200) | These investigate clinical effectiveness (‘proof of concept’), safety and dose–response relationship, often with a surrogate clinical endpoint, in the target patient group to determine the optimal dosing regimen for larger confirmatory studies | Duration: 1–2 years |
| Phase III | Patients (1000–10000) | These are large, expensive clinical trials that confirm safety and efficacy in the target patient population, using relevant clinical endpoints. They may be placebo-controlled studies or comparisons with other active compounds | Duration: 1–2 years |
| Phase IV | Patients (100s–1000s) | These are undertaken after the medicine has been marketed for its first indication to evaluate new indications, new doses or formulations, long-term safety or cost-effectiveness |

Responding when an error is discovered

All prescribers will make errors. When they do, their first duty is to protect the patient’s safety. This will involve a clinical review and the taking of any steps that will reduce harm (e.g. remedial treatment, monitoring, recording the event in the notes, informing colleagues). Patients should be informed if they have been exposed to potential harm. For errors that do not reach the patient, it is the prescriber’s duty to report them, so that others can learn from the experience and take the opportunity to reflect on how a similar incident might be avoided in the future.

Licensing new medicines

New drugs are given a ‘market authorisation’, based on the evidence of quality, safety and efficacy presented by the manufacturer. The regulator not only will approve the drug but also will take great care to ensure that the accompanying information reflects the evidence that has been presented. The summary of product characteristics (SPC), or ‘label’, provides detailed information about indications, dosage, adverse effects, warnings, monitoring and so on. If approved, drugs can be made available with different levels of restriction:

- Controlled drug (CD). These drugs are subject to strict legal controls on supply and possession, usually due to their abuse potential (e.g. opioid analgesics).
Prescription-only medicine (PoM). These are available only from a pharmacist and can be supplied only if prescribed by an appropriate practitioner.

Pharmacy (P). These are available only from a pharmacist but can be supplied without a prescription.

General sales list (GSL). These medicines may be bought ‘over the counter’ (OTC) from any shop and without a prescription.

Although the regulators take great care to agree the exact indications for prescribing a medicine, based on the evidence provided by the manufacturer, there are some circumstances in which prescribers may direct its use outside the terms stated in the SPC (‘off-label’ prescribing). Common situations where this might occur include prescribing outside the approved age group (e.g. prescribing for children) or using an alternative formulation (e.g. administering a medicine provided in a solid form as an oral solution). Other important examples might include prescribing for an indication for which there are no approved medicines or where all of the approved medicines have caused unacceptable adverse effects. Occasionally, medicines may be prescribed when there is no marketing authorisation in the country of use. Examples include when a medicine licensed in another country is imported for use for an individual patient (‘unlicensed import’) or when a patient requires a specific preparation of a medicine to be manufactured (‘unlicensed special’). When prescribing is ‘off-label’ or ‘unlicensed’, there is an increased requirement for prescribers to be able to justify their actions and to inform and agree the decision with the patient.

Managing the use of medicines

Many medicines meet the three key regulatory requirements of quality, safety and efficacy. Although prescribers are legally entitled to prescribe any of them, it is desirable to limit the choice so that treatments for specific diseases can be focused on the most effective and cost-effective options, prescribers (and patients) gain familiarity with a smaller number of medicines, and pharmacies can concentrate stocks on them.

The process of ensuring optimal use of available medicines is known as ‘medicines management’ or ‘quality use of medicines’. It involves careful evaluation of the evidence of benefit and harm from using the medicine, an assessment of cost-effectiveness, and support for processes to implement the resulting recommendations. These activities usually involve both national (e.g. National Institute for Health and Care Excellence (NICE) in the UK) and local organisations (e.g. drug and therapeutics committees).

Evaluating evidence

The principles of evidence-based medicine are described on page 10. Drugs are often evaluated in high-quality randomised controlled trials, the results of which can be considered by systematic review (Fig. 2.6). Ideally, data are available not only for comparison with placebo but also for ‘head-to-head’ comparison with alternative therapies. Trials are conducted in selected patient populations, however, and are not representative of every clinical scenario, so extrapolation to individual patients is not always straightforward. Other subtle bias may be introduced because of the sources of funding (e.g. pharmaceutical industry) and the interests of the investigators in being involved in research that has a ‘positive’ impact. These biases may be manifest in the way the trials are conducted or in how they are interpreted or reported. A common example of the latter is the difference between relative and absolute risk of clinical events reported in prevention trials. If a clinical event is encountered in the placebo arm at a rate of 1 in 50 patients (2%) but only 1 in 100 patients (1%) in the active treatment arm, then the impact of treatment can be described as either a 50% relative risk reduction or 1% absolute risk reduction. Although the former sounds more impressive, it is the latter that is of more importance to the patient.

Drug marketing

The marketing activities of the pharmaceutical industry are well resourced and are important in the process of recouping the massive costs of drug development. In some countries, such as the USA, it is possible to promote a new drug by direct-to-consumer advertising, although this is illegal in the countries of the European Union. A major focus is on promotion to prescribers via educational events, sponsorship of meetings, advertisements in journals, involvement with opinion leaders, and direct contact by company representatives. Such largesse has the potential to cause significant conflicts of interest and might tempt prescribers to favour one drug over another, even in the face of evidence on effectiveness or cost-effectiveness.
Evaluating cost-effectiveness

New drugs often represent an incremental improvement over the current standard of care but are usually more expensive. Health-care budgets are limited in every country and so it is impossible to fund all new medicines. This means that very difficult financial decisions have to be taken with due regard to the principles of ethical justice. The main approach taken is cost-effectiveness analysis (CEA), where a comparison is made between the relative costs and outcomes of different courses of action. CEA is usually expressed as a ratio where the denominator is the associated with the health gain. A major challenge is to compare the value of interventions for different clinical outcomes. One method is to calculate the quality-adjusted life years (QALYs) gained if the new drug is used rather than standard treatment. This analysis involves estimating the ‘utility’ of various health states between 1 (perfect health) and 0 (dead). If the additional costs and any savings are known, then it is possible to derive the incremental cost-effectiveness ratio (ICER) in terms of cost/QALY. These principles are exemplified in Box 2.16. There are, however, inherent weaknesses in this kind of analysis: it usually depends on modelling future outcomes well beyond the duration of the clinical trial data that are available; it assumes that QALYs gained at all ages are of equivalent value; and the appropriate standard care against which the new drug should be compared is often uncertain.

These pharmacoeconomic assessments are challenging and resource-intensive, and are undertaken at national level in most countries, e.g. in the UK by NICE.

Implementing recommendations

Many recommendations about drug therapy are included in clinical guidelines written by an expert group after systematic review of the evidence. Guidelines provide recommendations rather than obligations for prescribers and are helpful in promoting more consistent and higher-quality prescribing. They are often written without concern for cost-effectiveness, however, and may be limited by the quality of available evidence. Guidelines cannot anticipate the extent of the variation between individual patients who may, for example, have unexpected contraindications to recommended drugs or choose different priorities for treatment. When deviating from respected national guidance, prescribers should be able to justify their practice.

Additional recommendations for prescribing are often implemented locally or imposed by bodies responsible for paying for health care. Most health-care units have a drug and therapeutics committee (or equivalent) comprised of senior and junior medical staff, pharmacists and nurses, as well as managers (because of the implications of the committee’s work for governance and resources). This group typically develops local prescribing policy and guidelines, maintains a local drug formulary and evaluates requests to use new drugs. The local formulary contains a more limited list than any national formulary (e.g. British National Formulary) because the latter lists all licensed medicines that can be prescribed legally, while the former contains only those that the health-care organisation has approved for local use. The local committee may also be involved, with local specialists, in providing explicit protocols for management of clinical scenarios.

Prescribing in practice

Decision-making in prescribing

Prescribing should be based on a rational approach to a series of challenges (see Box 2.1).
Making a diagnosis
Ideally, prescribing should be based on a confirmed diagnosis but, in reality, many prescriptions are based on the balance of probability, taking into account the differential diagnosis (e.g. proton pump inhibitors for post-prandial retrosternal discomfort).

Establishing the therapeutic goal
The goals of treatment are usually clear, particularly when relieving symptoms (e.g. pain, nausea, constipation). Sometimes the goal is less obvious to the patient, especially when aiming to prevent future events (e.g. ACE inhibitors to prevent hospitalisation and extend life in chronic heart failure). Prescribers should be clear about the therapeutic goal against which they will judge success or failure of treatment. It is also important to establish that the value placed on this goal by the prescriber is shared by the patient (concordance).

Choosing the therapeutic approach
For many clinical problems, drug therapy is not absolutely mandated. Having taken the potential benefits and harms into account, prescribers must consider whether drug therapy is in the patient’s interest and is preferred to no treatment or one of a range of alternatives (e.g. psychotherapy, surgery). Assessing the balance of benefit and harm is often complicated and depends on various features associated with the patient, disease and drug (Box 2.17).

Choosing a drug
For most common clinical indications (e.g. type 2 diabetes, depression), more than one drug is available, often from more than one drug class. Although prescribers often have guidance about which represents the rational choice for the average patient, they still need to consider whether this is the optimal choice for the individual patient. Certain factors may influence the choice of drug:

Absorption
Patients may find some formulations easier to swallow than others or may be vomiting and require a drug available for parenteral administration.

Distribution
Distribution of a drug to a particular tissue sometimes dictates choice (e.g. tetracyclines and rifampicin are concentrated in the bile, and lincomycin and clindamycin in bones).

Metabolism
Drugs that are extensively metabolised should be avoided in severe liver disease (e.g. opioid analgesics).

Excretion
Drugs that depend on renal excretion for elimination (e.g. digoxin, aminoglycoside antibiotics) should be avoided in patients with impaired renal function if suitable alternatives exist.

Efficacy
Prescribers normally choose drugs with the greatest efficacy in achieving the goals of therapy (e.g. proton pump inhibitors rather than H₂-receptor antagonists). It may be appropriate, however, to compromise on efficacy if other drugs are more convenient, safer to use or less expensive.

Avoiding adverse effects
Prescribers should be wary of choosing drugs that are more likely to cause adverse effects (e.g. cephalosporins rather than alternatives for patients allergic to penicillin) or worsen coexisting conditions (e.g. β-blockers as treatment for angina in patients with asthma).

Features of the disease
This is most obvious when choosing antibiotic therapy, which should be based on the known or suspected sensitivity of the infective organism (p. 116).

Severity of disease
The choice of drug should be appropriate to disease severity (e.g. paracetamol for mild pain, morphine for severe pain).

Coexisting disease
This may be either an indication or a contraindication to therapy. Hypertensive patients might be prescribed a β-blocker if they also have left ventricular impairment but not if they have asthma.

Avoiding adverse drug interactions
Prescribers should avoid giving combinations of drugs that might interact, either directly or indirectly (see Box 2.11).

Patient adherence to therapy
Prescribers should choose drugs with a simple dosing schedule or easier administration (e.g. the ACE inhibitor Lisinopril once daily rather than captopril 3 times daily for hypertension).

Cost
Prescribers should choose the cheaper drug (e.g. a generic or biosimilar) if two drugs are of equal efficacy and safety. Even if cost is not a concern for the individual patient, it is important to remember that unnecessary expenditure will ultimately limit choices for other prescribers and patients. Sometimes a more costly drug may be appropriate (e.g. if it yields improved adherence).

Genetic factors
There are already a small number of examples where genotype influences the choice of drug therapy (see Box 2.5).

Choosing a dosage regimen
Prescribers have to choose a dose, route and frequency of administration (dosage regimen) to achieve a steady-state drug concentration that provides sufficient exposure of the target tissue without producing toxic effects. Manufacturers draw up dosage recommendations based on average observations in many patients but the optimal regimen that will maximise the benefit to harm ratio for an individual patient is never certain.

2.17 Factors to consider when balancing benefits and harms of drug therapy
- Seriousness of the disease or symptom
- Efficacy of the drug
- Seriousness of potential adverse effects
- Likelihood of adverse effects
- Efficacy of alternative drugs or non-drug therapies
- Safety of alternative drugs or non-drug therapies
Rational prescribing involves treating each prescription as an experiment and gathering sufficient information to amend it if necessary. There are some general principles that should be followed, as described below.

Dose titration
Prescribers should generally start with a low dose and titrate this slowly upwards as necessary. This cautious approach is particularly important if the patient is likely to be more sensitive to adverse pharmacodynamic effects (e.g. delirium or postural hypotension in the elderly) or have altered pharmacokinetic handling (e.g. renal or hepatic impairment), and when using drugs with a low therapeutic index (e.g. benzodiazepines, lithium, digoxin). There are some exceptions, however. Some drugs must achieve therapeutic concentration quickly because of the clinical circumstance (e.g. antibiotics, glucocorticoids, carbimazole). When early effect is important but there may be a delay in achieving steady state because of a drug’s long half-life (e.g. digoxin, warfarin, amiodarone), an initial loading dose is given prior to establishing the appropriate maintenance dose (see Fig. 2.4).

If adverse effects occur, the dose should be reduced or an alternative drug prescribed; in some cases, a lower dose may suffice if it can be combined with another synergistic drug (e.g. the immunosuppressant azathioprine reduces glucocorticoid requirements in patients with inflammatory disease). It is important to remember that the shape of the dose–response curve (see Fig. 2.2) means that higher doses may produce little added therapeutic effect and might increase the chances of toxicity.

Route
There are many reasons for choosing a particular route of administration (Box 2.18).

Frequency
Frequency of doses is usually dictated by a manufacturer’s recommendation. Less frequent doses are more convenient for patients but result in greater fluctuation between peaks and troughs in drug concentration (see Fig. 2.4). This is relevant if the peaks are associated with adverse effects (e.g. dizziness with antihypertensives) or the troughs are associated with troublesome loss of effect (e.g. anti-Parkinsonian drugs). These problems can be tackled either by splitting the dose or by employing a modified-release formulation, if available.

Timing
For many drugs the time of administration is unimportant. There are occasionally pharmacokinetic or therapeutic reasons, however, for giving drugs at particular times (Box 2.19).

Formulation
For some drugs there is a choice of formulation, some for use by different routes. Some are easier to ingest, particularly by children (e.g. elixirs). The formulation is important when writing repeat prescriptions for drugs with a low therapeutic index that come in different formulations (e.g. lithium, phenytoin, theophylline). Even if the prescribed dose remains constant, an alternative formulation may differ in its absorption and bioavailability, and hence plasma drug concentration. These are examples of the small number of drugs that should be prescribed by specific brand name rather than ‘generic’ international non-proprietary name (INN).

<td>Ease of access</td>
<td>Diazepam (PR, if IV access is difficult in status epilepticus)</td>
</tr>
<tr>
<td>Comfort</td>
<td>Morphine (SC rather than IV in terminal care)</td>
</tr>
</tbody>
</table>

Duration
Some drugs require a single dose (e.g. thrombolysis post myocardial infarction), while for others the duration of the course of treatment is certain at the outset (e.g. antibiotics). For most, the duration will be largely at the prescriber’s discretion and will depend on response and disease progression (e.g. analgesics, antidepressants). For many, the treatment will be long-term (e.g. insulin, antihypertensives, levothyroxine).

Involving the patient
Patients should, whenever possible, be engaged in making choices about drug therapy. Their beliefs and expectations affect the goals of therapy and help in judging the acceptable benefit/harm balance when selecting treatments. Very often, patients may wish to defer to the professional expertise of the prescriber. Nevertheless, they play key roles in adherence to therapy and in monitoring treatment, not least by providing early warning of adverse events. It is important for them to be provided with the necessary information to understand the choice that has been made, what to expect from the treatment, and any measurements that must be undertaken (Box 2.20).

A major drive to include patients has been the recognition that up to half of the drug doses for chronic preventative therapy are not taken. This is often termed ‘non-compliance’ but is more appropriately called ‘non-adherence’, to reflect a less paternalistic view of the doctor–patient relationship; it may or may not be intentional. Non-adherence to the dose regimen reduces the likelihood of benefits to the patient and can be costly in terms
of wasted medicines and unnecessary health-care episodes. An important reason may be lack of concordance with the prescriber about the goals of treatment. A more open and shared decision-making process might resolve any misunderstandings at the outset and foster improved adherence, as well as improved satisfaction with health-care services and confidence in prescribers. Fully engaging patients in shared decision-making is sometimes constrained by various factors, such as limited consultation time and challenges in communicating complex numerical data.

### Writing the prescription

The culmination of the planning described above is writing an accurate and legible prescription so that the drug will be dispensed and administered as planned (see ‘Writing prescriptions’ below).

### Monitoring treatment effects

Rational prescribing involves monitoring for the beneficial and adverse effects of treatment so that the balance remains in favour of a positive outcome (see ‘Monitoring drug therapy’ below).

---

### Stopping drug therapy

It is also important to review long-term treatment at regular intervals to assess whether continued treatment is required. Elderly patients are keen to reduce their medication burden and are often prepared to compromise on the original goals of long-term preventative therapy to achieve this.

### Prescribing in special circumstances

#### Prescribing for patients with renal disease

Patients with renal impairment are readily identified by having a low estimated glomerular filtration rate (eGFR <60 mL/min) based on their serum creatinine, age, sex and ethnic group (p. 386). This group includes a large proportion of elderly patients. If a drug (or its active metabolites) is eliminated predominantly by the kidneys, it will tend to accumulate and so the maintenance dose must be reduced. For some drugs, renal impairment makes patients more sensitive to their adverse pharmacodynamic effects.
About 35% of women take drug therapy at least once during pregnancy (e.g. morning sickness, anaemia, prevention of epilepsy, asthma, hypothyroidism) or for problems that may, however, be required either for a pre-existing problem (e.g. insulin (hypoglycaemia) and warfarin). Prescribing in pregnancy should be avoided if possible to minimise adverse effects on the fetus. Drug therapy in pregnancy may, however, be required either for a pre-existing problem (e.g. epilepsy, asthma, hypothyroidism) or for problems that arise during pregnancy (e.g. morning sickness, anaemia, prevention of neural tube defects, gestational diabetes, hypertension). About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folate acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. Some considerations when prescribing in pregnancy are listed in Box 2.23.

### 2.21 Some drugs that require extra caution in patients with renal or hepatic disease

Pharmacokinetic handling altered (reduced clearance)

| Aminoglycosides (e.g. gentamicin) | Phenytoin |
| Vancomycin | Rifampicin |
| Digoxin | Propranolol |
| Lithium | Warfarin |
| Other antibiotics (e.g. ciprofloxacin) | Diazepam |
| Atenolol | Lidocaine |
| Allopurinol | Opioids (e.g. morphine) |
| Cephalosporins | Methotrexate |
| | Opioids (e.g. morphine) |

(ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; NSAID = non-steroidal anti-inflammatory drug)

Examples of drugs that require extra caution in patients with renal disease are listed in Box 2.21.

### Prescribing for patients with hepatic disease

The liver has a large capacity for drug metabolism and hepatic insufficiency has to be advanced before drug dosages need to be modified. Patients who may have impaired metabolism include those with jaundice, ascites, hypalbuminemia, malnutrition or encephalopathy. Hepatic drug clearance may also be reduced in acute hepatitis, in hepatic congestion due to cardiac failure, and in the presence of intrahepatic arteriovenous shunting (e.g. in hepatitis cirrhosis). There are no good tests of hepatic drug-metabolising capacity or of biliary excretion, so dosage should be guided by the therapeutic response and careful monitoring for adverse effects. The presence of liver disease also increases the susceptibility to adverse pharmacological effects of drugs. Some drugs that require extra caution in patients with hepatic disease are listed in Box 2.21.

### Prescribing for elderly patients

The issues around prescribing in the elderly are discussed in Box 2.22.

### Prescribing for women who are pregnant or breastfeeding

Prescribing in pregnancy should be avoided if possible to minimise the risk of adverse effects on the fetus. Drug therapy in pregnancy may, however, be required either for a pre-existing problem (e.g. epilepsy, asthma, hypothyroidism) or for problems that arise during pregnancy (e.g. morning sickness, anaemia, prevention of neural tube defects, gestational diabetes, hypertension). About 35% of women take drug therapy at least once during pregnancy and 6% take drug therapy during the first trimester (excluding iron, folic acid and vitamins). The most commonly used drugs are simple analgesics, antibacterial drugs and antacids. Some considerations when prescribing in pregnancy are listed in Box 2.23.

### 2.22 Prescribing in old age

- **Reduced drug elimination**: partly due to impaired renal function.
- **Increased sensitivity to drug effects**: notably in the brain (leading to sedation or delirium) and as a result of comorbidities.
- **More drug interactions**: largely as a result of polypharmacy.
- **Lower starting doses and slower dose titration**: often required, with careful monitoring of drug effects.
- **Drug adherence**: may be poor because of cognitive impairment, difficulty swallowing (dry mouth) and complex polypharmacy regimens. Supplying medicines in pill organisers (e.g. dosette boxes or calendar blister packs), providing automatic reminders, and regularly reviewing and simplifying the drug regimen can help.

### 2.23 Prescribing in pregnancy

- **Teratogenesis**: a potential risk, especially when drugs are taken between 2 and 8 weeks of gestation (4–10 weeks from last menstrual period). Common teratogens include retinoids (e.g. isotretinoin), cytotoxic drugs, angiotensin-converting enzyme inhibitors, antiepileptics and warfarin. If there is inadvertent exposure, then the timing of conception should be established, counselling given and investigations undertaken for fetal abnormalities.
- **Adverse fetal effects in late gestation**: e.g. tetracyclines may stain growing teeth and bones; sulphonamides displace fetal bilirubin from plasma proteins, potentially causing kernicterus; opioids given during delivery may be associated with respiratory depression in the neonate.
- **Altered maternal pharmacokinetics**: extracellular fluid volume and Vd increase. Plasma albumin falls but other binding globulins (e.g. for thyroid and steroid hormones) increase. Glomerular filtration increases by approximately 70%, enhancing renal clearance. Placental metabolism contributes to increased clearance, e.g. of levothyroxine and glucocorticoids. The overall effect is a fall in plasma levels of many drugs.
- **In practice**: Avoid any drugs unless the risk/benefit analysis is in favour of treating (usually the mother). Use drugs for which there is some record of safety in humans. Use the lowest dose for the shortest time possible. Choose the least harmful drug if alternatives are available.
Drugs that are excreted in breast milk may cause adverse effects in the baby. Prescribers should always consult the summary of product characteristics for each drug or a reliable formulary when treating a pregnant woman or breastfeeding mother.

Writing prescriptions

A prescription is a means by which a prescriber communicates the intended plan of treatment to the pharmacist who dispenses a medicine and to a nurse or patient who administers it. It should be precise, accurate, clear and legible. The two main kinds of prescription are those written, dispensed and administered in hospital and those written in primary care (in the UK by a GP), dispensed at a community pharmacy and self-administered by the patient. The information supplied must include:

- the date
- the identification details of the patient
- the name of the drug
- the formulation
- the dose
- the frequency of administration
- the route and method of administration
- the amount to be supplied (primary care only)
- instructions for labelling (primary care only)
- the prescriber’s signature.

Prescribing in hospital

Although GP prescribing is increasingly electronic, most hospital prescribing continues to be based around the prescription and administration record (the ‘drug chart’) (Fig. 2.7). A variety of charts are in use and prescribers must familiarise themselves with the local version. Most contain the following sections:

- **Basic patient information:** will usually include name, age, date of birth, hospital number and address. These details are often ‘filled in’ using a sticky addressograph label but this increases the risk of serious error.
- **Previous adverse reactions/allergies:** communicates important patient safety information based on a careful drug history and/or the medical record.
- **Other medicines charts:** notes any other hospital prescription documents that contain current prescriptions being received by the patient (e.g. anticoagulants, insulin, oxygen, fluids).
- **Once-only medications:** for prescribing medicines to be used infrequently, such as single-dose prophylactic antibiotics and other pre-operative medications.
- **Regular medications:** for prescribing medicines to be taken for a number of days or continuously, such as a course of antibiotics, antihypertensive drugs and so on.
- **‘As required’ medications:** for prescribing for symptomatic relief, usually to be administered at the discretion of the nursing staff (e.g. antiemetics, analgesics).

Prescribers should be aware of the risks of prescription error (Box 2.24 and see Box 2.13), ensure they have considered the rational basis for their prescribing decision described above, and then follow the guidance illustrated in Figure 2.7 in order to write the prescription. It is a basic principle that a prescription will be followed by a judgement as to its success or failure and any appropriate changes made (e.g. altered dosage, discontinuation or substitution).

### Box 2.24 High-risk prescribing moments

- **Trying to amend an active prescription (e.g. altering the dose/timing) – always avoid and start again**
- **Writing up drugs in the immediate presence of more than one prescription chart or set of notes – avoid**
- **Allowing one’s attention to be diverted in the middle of completing a prescription – avoid**
- **Prescribing ‘high-risk’ drugs (e.g. anticoagulants, opioids, insulin, sedatives) – ask for help if necessary**
- **Prescribing parenteral drugs – take care**
- **Rushing prescribing (e.g. in the midst of a busy ward round) – avoid**
- **Prescribing unfamiliar drugs – consult the formulary and ask for help if necessary**
- **Transcribing multiple prescriptions from an expired chart to a new one – take care to review the rationale for each medicine**
- **Writing prescriptions based on information from another source such as a referral letter (the list may contain errors and some of the medicines may be the cause of the patient’s illness) – review the justification for each as if it is a new prescription**
- **Writing up ‘to take out’ drugs (because these will become the patient’s regular medication for the immediate future) – take care and seek advice if necessary**
- **Calculating drug doses – ask a colleague to perform an independent calculation or use approved electronic dose calculators**
- **Prescribing sound-alike or look-alike drugs (e.g. chlorphenamine and chlorpromazine) – take care**

Hospital discharge (‘to take out’) medicines

Most patients will be prescribed a short course of their medicines at discharge. This prescription is particularly important because it usually informs future therapy at the point of transfer of prescribing responsibility to primary care. Great care is required to ensure that this list is accurate. It is particularly important to ensure that any hospital medicines that should be stopped are not included and that those intended to be administered for a short duration only are clearly identified. It is also important for any significant ADRs experienced in hospital to be recorded and any specific monitoring or review identified.

Prescribing in primary care

Most of the considerations above are equally applicable to primary care (GP) prescriptions. In many health-care systems, community prescribing is electronic, making issues of legibility irrelevant and often providing basic decision support to limit the range of doses that can be written and highlight potential drug interactions. Important additional issues more relevant to GP prescribing are:

- **Formulation.** The prescription needs to carry information about the formulation for the dispensing pharmacist (e.g. tablets or oral suspension).
- **Amount to be supplied.** In the hospital the pharmacist will organise this. Elsewhere it must be specified either as the precise number of tablets or as the duration of treatment. Creams and ointments should be specified in grams and lotions in mL.
- **Controlled drugs.** Prescriptions for ‘controlled’ drugs (e.g. opioid analgesics, with potential for drug abuse) are subject to additional legal requirements. In the UK, they...

Fig. 2.7 Example of a hospital prescription and administration record (‘drug chart’). A Front page. The correct identification of the patient is critical to reducing the risk of an administration error. This page also clearly identifies other prescriptions charts in use and previous adverse reactions to drugs to minimise the risk of repeated exposure. Note also the codes employed by the nursing staff to indicate reasons why drugs may not have been administered. The patient’s name and date of birth should be written on each page of the chart. The patient’s weight and height may be required to calculate safe doses for many drugs with narrow therapeutic indices. B ‘Once-only medicines’. This area is used for prescribing medicines that are unlikely to be repeated on a regular basis. Note that the prescriber has written the names of all drugs legibly in block capitals. The generic international non-proprietary name (INN) should be used in preference to the brand name (e.g. write ‘SIMVASTATIN’, not ‘ZOCOR’). The only exceptions are when variation occurs in the properties of alternative branded formulations (e.g. modified-release preparations of drugs such as lithium, theophylline, phenytoin and nifedipine) or when the drug is a combination product with no generic name (e.g. Kliovance). The only acceptable abbreviations for drug dose units are ‘g’ and ‘mg’. ‘Units’ (e.g. of insulin or heparin) and ‘micrograms’ must always be written in full, never as ‘U’ or ‘μg’ (nor ‘mcg’, nor ‘ug’). For liquid preparations write the dose in mg; ‘mL’ can be written only for a combination product (e.g. Gaviscon liquid) or if the strength is not expressed in weight (e.g. adrenaline (epinephrine) 1 in 1000). Use numbers/figures (e.g. 1 or ‘one’) to denote use of a sachet/enema but avoid prescribing numbers of tablets without specifying their strength. Always include the dose of inhaled drugs in addition to stating numbers of ‘puffs’, as strengths can vary. Widely accepted abbreviations for route of administration are: intravenous – ‘IV’; intramuscular – ‘IM’; subcutaneous – ‘SC’; sublingual – ‘SL’; per rectum – ‘PR’; per vaginam – ‘PV’; nasogastric – ‘NG’; inhaled – ‘INH’; and topical – ‘TOP’. ‘ORAL’ is preferred to per oram – ‘PO’. Care should be taken in specifying ‘RIGHT’ or ‘LEFT’ for eye and ear drops. The prescriber should sign and print their name clearly so that they can be identified by colleagues. The prescription should be dated and have an administration time. The nurse who administered the prescription has signed to confirm that the dose has been administered.

must contain the address of the patient and prescriber (not necessary on most hospital forms), the form and the strength of the preparation, and the total quantity of the preparation/number of dose units in both words and figures.

‘Repeat prescriptions’. A large proportion of GP prescribing involves ‘repeat prescriptions’ for chronic medication. These are often generated automatically, although the prescriber remains responsible for regular review and for ensuring that the benefit-to-harm ratio remains favourable.

Monitoring drug therapy

Prescribers should measure the effects of the drug, both beneficial and harmful, to inform decisions about dose titration (up or down), discontinuation or substitution of treatment. Monitoring can be achieved subjectively by asking the patient about symptoms or, more objectively, by measuring a clinical effect. Alternatively, if the pharmacodynamic effects of the drug are difficult to assess, the plasma drug concentration may be measured, on the basis that it will be closely related to the effect of the drug (see Fig. 2.2).
Regular medicines.

This area is used for prescribing medicines that are going to be given regularly. In addition to the name, dose and route, a frequency of administration is required for each medicine. Widely accepted Latin abbreviations for dose frequency are: once daily – ‘OD’; twice daily – ‘BD’; 3 times daily – ‘TDS’; 4 times daily – ‘QDS’; as required – ‘PRN’; in the morning – ‘OM’ (omni mane); at night – ‘ON’ (omni nocte); and immediately – ‘stat’. The hospital chart usually requires specific times to be identified for regular medicines that coincide with nursing drug rounds and these can be circled. If treatment is for a known time period, cross off subsequent days when the medicine is not required. The ‘notes’ box can be used to communicate additional important information (e.g. whether a medicine should be taken with food, type of inhaler device used, and anything else that the drug dispenser should know). State here the times for peak/trough plasma levels for drugs requiring therapeutic monitoring. Prescriptions should be discontinued by drawing a vertical line at the point of discontinuation, horizontal lines through the remaining days on the chart, and diagonal lines through the drug details and administration boxes. This action should be signed and dated and a supplementary note written to explain it (e.g. describing any adverse effect). In this example, amlodipine has been discontinued because of ankle oedema. There is room for the ward pharmacist to sign to indicate that the prescription has been reviewed and that a supply of the medicine is available. The administration boxes allow the nurse to sign to confirm that the dose has been given. Note that these boxes also allow for recording of reasons for non-administration (in this example ‘2’ indicates that the patient was not present on the ward at the time) and the prevention of future administration by placing an ‘X’ in the box.

As-required medicines.

These prescriptions leave the administration of the drug to the discretion of the nursing staff. The prescription must describe clearly the indication, frequency, minimal time interval between doses, and maximum dose in any 24-hour period (in this case, the maximum daily dose of paracetamol is 4 g).

Clinical and surrogate endpoints

Ideally, clinical endpoints are measured directly and the drug dosage titrated to achieve the therapeutic goal and avoid toxicity (e.g. control of ventricular rate in a patient with atrial fibrillation). Sometimes this is impractical because the clinical endpoint is a future event (e.g. prevention of myocardial infarction by statins or resolution of a chest infection with antibiotics); in these circumstances, it may be possible to select a ‘surrogate’ endpoint that will predict success or failure. This may be an intermediate step in the pathophysiological process (e.g. serum cholesterol as a surrogate for risk of myocardial infarction) or a
measurement that follows the pathophysiology, even if it is not a key factor in its progression (e.g. serum C-reactive protein as a surrogate for resolution of inflammation in chest infection). Such surrogates are sometimes termed ‘biomarkers’.

**Plasma drug concentration**

The following criteria must be met to justify routine monitoring by plasma drug concentration:

- Clinical endpoints and other pharmacodynamic (surrogate) effects are difficult to monitor.
- The relationship between plasma concentration and clinical effects is predictable.
- The therapeutic index is low. For drugs with a high therapeutic index, any variability in plasma concentrations is likely to be irrelevant clinically.

Some examples of drugs that fulfil these criteria are listed in Box 2.25.

Measurement of plasma concentration may be useful in planning adjustments of drug dose and frequency of administration; to explain an inadequate therapeutic response (by identifying subtherapeutic concentration or incomplete adherence); to establish whether a suspected ADR is likely to be caused by the drug; and to assess and avoid potential drug interactions.

**Timing of samples in relation to doses**

The concentration of drug rises and falls during the dosage interval (see Fig. 2.4B). Measurements made during the initial absorption and distribution phases are unpredictable because of the rapidly changing concentration, so samples are usually taken at the end of the dosage interval (a ‘trough’ or ‘pre-dose’ concentration). This measurement is normally made in steady state, which usually takes five half-lives to achieve after the drug is introduced or the dose changed (unless a loading dose has been given).

**Interpreting the result**

A target range is provided for many drugs, based on average thresholds for therapeutic benefit and toxicity. Inter-individual variability means that these can be used only as a guide. For instance, in a patient who describes symptoms that could be consistent with toxicity but has a drug concentration in the top half of the target range, toxic effects should still be suspected. Another important consideration is that some drugs are heavily protein-bound (e.g. phenytoin) but only the unbound drug is pharmacologically active. Patients with hypoalbuminaemia may therefore have a therapeutic or even toxic concentration of unbound drug, despite a low ‘total’ concentration.

We have entered a genomic era. Powerful new technologies are driving forward transformational change in health care. Genetic sequencing has evolved from the targeted sequencing of a single gene to the parallel sequencing of multiple genes. In addition to improving the chances of identifying a genetic cause of rare diseases, these technologies are increasingly directing therapies and, in the future, are likely to be used in the diagnosis and prevention of common diseases such as diabetes. In this chapter we explore the fundamentals of genomics, the basic principles underlying these new genomic technologies and how the data generated can be applied safely for patient benefit. We will review the use of genomic technology across a breadth of medical specialties, including obstetrics, paediatrics, oncology and infectious disease, and consider how health care is likely to be transformed by technology over the coming decade. Finally, we will consider the ethical impact that these technologies are likely to have, both for the individual and for their wider family.

The fundamental principles of genomics

The packaging of genes: DNA, chromatin and chromosomes

Genes are functional units encoded in double-stranded deoxyribonucleic acid (DNA), packaged as chromosomes and located in the nucleus of the cell: a membrane-bound compartment found in all cells except erythrocytes and platelets (Fig. 3.1). DNA consists of a linear sequence of just four bases: adenine (A), cytosine (C), thymine (T) and guanine (G). It forms a ‘double helix’, a twisted ladder-like structure formed from two complementary strands of DNA joined by hydrogen bonds between bases on the opposite strand that can form only between a C and a G base and an A and a T base. It is this feature of DNA that enables faithful DNA replication and is the basis for many of the technologies designed to interrogate the genome: when the DNA double helix ‘unzips’, one strand can act as a template for the creation of an identical strand.

A single copy of the human genome comprises approximately 3.1 billion base pairs of DNA, wound around proteins called histones. The unit consisting of 147 base pairs wrapped around four different histone proteins is called the nucleosome. Sequences of nucleosomes (resembling a string of beads) are wound and packaged to form chromatin: tightly wound, densely packed chromatin is called heterochromatin and open, less tightly wound chromatin is called euchromatin.

The chromatin is finally packaged into the chromosomes. Humans are diploid organisms: the nucleus contains two copies of the genome, visible microscopically as 23 chromosome pairs (known as the karyotype). Chromosomes 1 through to 22 are known as the autosomes and consist of identical chromosomal pairs. The 23rd ‘pair’ of chromosomes are the two sex chromosomes: females have two X chromosomes and males an X and Y chromosome. A normal female karyotype is therefore written as 46,XX and a normal male is 46,XY.

From DNA to protein

Genes are functional elements on the chromosome that are capable of transmitting information from the DNA template via the production of messenger ribonucleic acid (mRNA) to the production of proteins. The human genome contains over 20,000 genes, although many of these are inactive or silenced in different cell types, reflecting the variable gene expression responsible for cell-specific characteristics. The central dogma is the pathway describing the basic steps of protein production: transcription, splicing, translation and protein modification (Fig. 3.2). Although this is now recognised as an over-simplification (contrary to this linear relationship, a single gene will often encode many different proteins), it remains a useful starting point to explore protein production.

Transcription: DNA to messenger RNA

Transcription describes the production of ribonucleic acid (RNA) from the DNA template. For transcription to commence, an enzyme called RNA polymerase binds to a segment of DNA at the start of the gene: the promoter. Once bound, RNA polymerase moves along one strand of DNA, producing an RNA molecule complementary to the DNA template. In protein-coding genes this is known as messenger RNA (mRNA). A DNA sequence close to the end of the gene, called the polyadenylation signal, acts as a signal for termination of the RNA transcript (Fig. 3.3).
The fundamental principles of genomics

RNA differs from DNA in three main ways:
- RNA is single-stranded.
- The sugar residue within the nucleotide is ribose, rather than deoxyribose.
- It contains uracil (U) in place of thymine (T).

The activity of RNA polymerase is regulated by transcription factors. These proteins bind to specific DNA sequences at the promoter or to enhancer elements that may be many thousands of base pairs away from the promoter; a loop in the chromosomal DNA brings the enhancer close to the promoter, enabling the bound proteins to interact. The human genome encodes more than 1200 different transcription factors. Mutations within transcription factors, promoters and enhancers can cause disease. For example, the blood disorder alpha-thalassaemia is usually caused by gene deletions (see p. 954 and Box 3.4). However, it can also result from a mutation in an enhancer located more than 100,000 base pairs (bp) from the α-globin gene promoter, leading to greatly reduced transcription.

Gene activity, or expression, is influenced by a number of complex interacting factors, including the accessibility of the gene promoter to transcription factors. DNA can be modified by the addition of a methyl group to cytosine molecules (methylation). If DNA methylation occurs in promoter regions, transcription is silenced, as methyl cytosines are usually not available for transcription factor binding. A second mechanism determining promoter accessibility is the structural configuration of chromatin. In open chromatin, called euchromatin, gene promoters are accessible to RNA polymerase and transcription factors; therefore it is transcriptionally active. This contrasts with heterochromatin, which is densely packed and transcriptionally silent. The chromatin configuration is determined by modifications (such as methylation or acetylation) of specific amino acid residues of histone protein tails.

Modifications of DNA and histones are termed epigenetic (‘epi’ meaning ‘above’ the genome), as they do not alter the primary sequence of the DNA code but have biological significance in chromosomal function. Abnormal epigenetic changes are increasingly recognised as important events in the progression of cancer, allowing expression of normally silenced genes that result in cancer cell de-differentiation and proliferation. They also afford therapeutic targets. For instance, the histone deacetylase inhibitor vorinostat has been successfully used to treat cutaneous T-cell lymphoma, due to the re-expression of genes that had
previously been silenced in the tumour. These genes encode
transcription factors that promote T-cell differentiation as opposed
to proliferation, thereby causing tumour regression.

### RNA splicing, editing and degradation

Transcription produces an RNA molecule that is a copy of the
whole gene, termed the primary or nascent transcript. This
nascent transcript then undergoes splicing, whereby regions
not required to make protein (the intronic regions) are removed
while those segments that are necessary for protein production
(the exonic regions) are retained and rejoined.

Splicing is a highly regulated process that is carried out by a
multimeric protein complex called the spliceosome. Following
splicing, the mRNA molecule is exported from the nucleus and
used as a template for protein synthesis. Many genes produce
more than one form of mRNA (and thus protein) by a process
termed alternative splicing, in which different combinations of
exons are joined together. Different proteins from the
same gene can have entirely distinct functions. For example, in
thyroid C cells the calcitonin gene produces mRNA encoding
the osteoclast inhibitor calcitonin (p. 634), but in neurons the
same gene produces an mRNA with a different complement of
exons via alternative splicing that encodes a neurotransmitter,
calcitonin-gene-related peptide (p. 772).

### Translation and protein production

Following splicing, the segment of mRNA containing the code
that directs synthesis of a protein product is called the open
reading frame (ORF). The inclusion of a particular amino acid
in the protein is specified by a codon composed of three contiguous
bases. There are 64 different codons with some redundancy in
the system: 61 codons encode one of the 20 amino acids, and
the remaining three codons – UAA, UAG and UGA (known as
stop codons) – cause termination of the growing polypeptide
chain. ORFs in humans most commonly start with the amino
acid methionine. All mRNA molecules have domains before and
after the ORF called the 5′ untranslated region (UTR) and 3′UTR,
respectively. The start of the 5′ UTR contains a cap structure that
protects mRNA from enzymatic degradation, and other elements
within the 5′ UTR are required for efficient translation. The 3′UTR
also contains elements that regulate efficiency of translation and
mRNA stability, including a stretch of adenine bases known as
a polyA tail (see Fig. 3.3).

The mRNAs then leave the nucleus via nuclear pores and
associate with ribosomes, the sites of protein production (see
Fig. 3.3). Each ribosome consists of two subunits (40S and
60S), which comprise non-coding rRNA molecules (see Fig. 3.9,
p. 50) complexed with proteins. During translation, a different RNA
molecule known as transfer RNA (tRNA) binds to the ribosome.
The tRNAs deliver amino acids to the ribosome so that the newly
translated protein can be assembled in a stepwise fashion.
Individual tRNA molecules bind a specific amino acid and ‘read’
the mRNA ORF via an ‘anticodon’ of three nucleotides that is
complementary to the codon in mRNA (see Fig. 3.3). A proportion
of ribosomes is bound to the membrane of the endoplasmic reticulum
(ER), a complex tubular structure that surrounds the nucleus.
Proteins synthesised on these ribosomes are translocated
into the lumen of the ER, where they undergo folding and
processing. From here, the protein may be transferred to
the Golgi apparatus, where it undergoes post-translational
modifications, such as glycosylation (covalent attachment of
sugar moieties), to form the mature protein that can be exported
into the cytoplasm or packaged into vesicles for secretion.
The clinical importance of post-translational modification of
proteins is shown by the severe developmental, neurological,
haemostatic and soft tissue abnormalities that are associated
with the many different congenital disorders of glycosylation.
Post-translational modifications can also be disrupted by the
synthesis of proteins with abnormal amino acid sequences. For
example, the most common mutation in cystic fibrosis (AF508)
results in an abnormal protein that cannot be exported from the
ER and Golgi (see Box 3.4).

### Non-coding RNA

Approximately 4500 genes in humans encode non-coding RNAs
(ncRNA) rather than proteins. There are various categories of
ncRNA, including transfer RNA (tRNA), ribosomal RNA (rRNA),
ribozymes and microRNA (miRNA). The miRNAs, which number
over 1000, have a role in post-translational gene expression:
they bind to mRNAs, typically in the 3′UTR, promoting target
mRNA degradation and gene silencing. Together, miRNAs affect
over half of all human genes and have important roles in normal
development, cancer and common degenerative disorders.
This is the subject of considerable research interest at present.

### Cell division, differentiation and migration

In normal tissues, molecules such as hormones, growth factors
and cytokines provide the signal to activate the cell cycle: a
controlled programme of biochemical events that culminates in
cell division. In all cells of the body, except the gametes (the sperm
and egg cells, also known as the germ line), mitosis completes
cell division, resulting in two diploid daughter cells. In contrast,
the sperm and eggs cells complete cell division with meiosis,
resulting in four haploid daughter cells (Fig. 3.4).

The stages of cell division in the non-germ-line, somatic cells
are shown below:

- **Cells not committed to mitosis** are said to be in G0.
- **Cells committed to mitosis** must go through the
  preparatory phase of interphase consisting of G1, S and G2:
  - G1 (first gap): synthesis of the cellular components
    necessary to complete cell division
  - S (synthesis): DNA replication producing identical
copies of each chromosome called the sister chromatids
  - G2 (second gap): repair of any errors in the replicated
DNA before proceeding to mitosis.
- **Mitosis (M)** consists of four phases:
  - Prophase: the chromosomes condense and become
    visible, the centrioles move to opposite ends of the cell
    and the nuclear membrane disappears.
  - Metaphase: the centrioles complete their migration to
    opposite ends of the cell and the chromosomes –
    consisting of two identical sister chromatids – line up at
    the equator of the cell.
  - Anaphase: spindle fibres attach to the chromosome
    and pull the sister chromatids apart.
  - Telophase: the chromosomes decondense, the nuclear
    membrane reforms and two daughter cells – each with
    46 chromosomes – are formed.

The progression from one phase to the next is tightly controlled
by cell-cycle checkpoints. For example, the checkpoint between
The fundamental principles of genomics

• Meiosis is a special, gamete-specific, form of cell division (Fig. 3.4). Like mitosis, meiosis consists of four phases (prophase, metaphase, anaphase and telophase) but differs from mitosis in the following ways:
  • It consists of two separate cell divisions known as meiosis I and meiosis II.
  • It reduces the chromosome number from the diploid to the haploid number via a tetraploid stage, i.e. from 46 to 92 (MI S) to 46 (MI M) to 23 (MII M) chromosomes, so that when a sperm cell fertilises the egg, the resulting zygote will return to a diploid, 46, chromosome complement. This reduction to the haploid number occurs at the end of meiosis II.
  • The 92 chromosome stage consists of 23 homologous pairs of sister chromatids, which then swap genetic material, a process known as recombination. This occurs at the end of MI prophase and ensures that the chromosome that a parent passes to his or her offspring is a mix of the chromosomes that the parent inherited from his or her own mother and father.

The individual steps in meiotic cell division are similar in males and females. However, the timing of the cell divisions is very different. In females, meiosis begins in fetal life but does not complete until after ovulation. A single meiotic cell division can thus take more than 40 years to complete. As women become older, the separation of chromosomes at meiosis II becomes less efficient. That is why the risk of trisomies (p. 44) due to non-disjunction grows greater with increasing maternal age.

In males, meiotic division does not begin until puberty and continues throughout life. In the testes, both meiotic divisions are completed in a matter of days.

Cell death, apoptosis and senescence

With the exception of stem cells, human cells have only a limited capacity for cell division. The Hayflick limit is the number of divisions a cell population can go through in culture before division stops and enters a state known as senescence. This “biological clock” is of great interest in the study of the normal ageing process. Rare human diseases associated with premature ageing, called progeric syndromes, have been very helpful in identifying the importance of DNA repair mechanisms in senescence (p. 1034). For example, in Werner’s syndrome, a DNA helicase (an enzyme that separates the two DNA strands) is mutated, leading to failure of DNA repair and premature ageing. A distinct mechanism of cell death is seen in apoptosis, or programmed cell death.

Apoptosis is an active process that occurs in normal tissues and plays an important role in development, tissue remodelling and the immune response. The signal that triggers apoptosis is specific to each tissue or cell type. This signal activates enzymes, called caspases, which actively destroy cellular components, including chromosomal DNA. This degradation results in cell death, but the cellular corpse contains characteristic vesicles called apoptotic bodies. The corpse is then recognised and removed by phagocytic cells of the immune system, such as macrophages, in a manner that does not provoke an inflammatory response.

A third mechanism of cell death is necrosis. This is a pathological process in which the cellular environment loses one or more of the components necessary for cell viability. Hypoxia is probably the most common cause of necrosis.
Genomics, health and disease

Classes of genetic variant

There are many different classes of variation in the human genome, categorised by the size of the DNA segment involved and/or by the mechanism giving rise to the variation.

Nucleotide substitutions

The substitution of one nucleotide for another is the most common type of genomic variation. Depending on their frequency and functional consequences, these changes are known as point mutations or single nucleotide polymorphisms (SNPs). They occur by misincorporation of a nucleotide during DNA synthesis or by chemical modification of the base. When these substitutions occur within ORFs of a protein-coding gene, they are further classified into:

- **synonymous** – resulting in a change in the codon without altering the amino acid
- **non-synonymous** (also known as a missense mutation) – resulting in a change in the codon and the encoded amino acid
- **stop gain** (also known as a nonsense mutation) – introducing a premature stop codon and resulting in truncation of the protein
- **splicing** – taking place at splice sites that most frequently occur at the junction between an intron and an exon.

These different types of mutation are illustrated in Box 3.1 and examples are shown in Figures 3.5 and 3.6.

Insertions and deletions

One or more nucleotides may be inserted or lost in a DNA sequence, resulting in an insertion/deletion (indel) polymorphism or mutation (Box 3.1 and Fig. 3.5). If a multiple of three nucleotides is involved, this is in-frame. If an indel change affects one or two nucleotides within the ORF of a protein-coding gene, this can have serious consequences because the triple nucleotide sequence of the codons is disrupted, resulting in a frameshift mutation. The effect on the gene is typically severe because the amino acid sequence is totally disrupted.

---

**Fig. 3.5** Different types of mutation affecting coding exons. **A** Normal sequence. **B** A synonymous nucleotide substitution changing the third base of a codon; the resulting amino acid sequence is unchanged. **C** A missense mutation in which the nucleotide substitution results in a change in a single amino acid from the normal sequence (AAG) encoding lysine to glutamine (CAG). **D** Insertion of a G residue (boxed) causes a frameshift mutation, completely altering the amino acid sequence downstream. This usually results in a loss-of-function mutation. **E** A nonsense mutation resulting in a single nucleotide change from a lysine codon (AAG) to a premature stop codon (TAG).
size of the original repeat, in that longer repeats tend to be more unstable. Many microsatellites and minisatellites occur in introns or in chromosomal regions between genes and have no obvious adverse effects. However, some genetic diseases are caused by microsatellite repeats that result in duplication of amino acids within the affected gene product or affect gene expression (Box 3.2).

*The triplet repeat diseases fall into two major groups: those with disease stemming from expansion of [CAG], repeats in coding DNA, resulting in multiple adjacent glutamine residues (polyglutamine tracts), and those with non-coding repeats. The latter tend to be longer. Unaffected parents usually display ‘pre-mutation’ allele lengths that are just above the normal range. (AD/AR = autosomal dominant/recessive; UTR = untranslated region; XL = X-linked)
Copy number variations

Variation in the number of copies of an individual segment of the genome from the usual diploid (two copies) content can be categorised by the size of the segment involved. Rarely, individuals may gain (trisomy) or lose (monosomy) a whole chromosome. Such numerical chromosome anomalies most commonly occur by a process known as non-disjunction, where pairs of homologous chromosomes do not separate at meiosis II (p. 40). Common trisomies include Down’s syndrome (trisomy 21), Edward’s syndrome (trisomy 18) and Patau’s syndrome (trisomy 13). Monosomy of the autosomes (present in all the cells, as opposed to in a mosaic distribution) does not occur but Turner’s syndrome, in which there is monosomy for the X chromosome, affects approximately 1 in 2500 live births (Box 3.3).

Large insertions or deletions of chromosomal DNA also occur and are usually associated with a learning disability and/or congenital malformations. Such structural chromosome anomalies usually arise as the result of one of two different processes:
- non-homologous end-joining
- non-allelic homologous recombination.

Random double-stranded breaks in DNA are a necessary process in meiotic recombination and also occur during mitosis at a predictable rate. The rate of these breaks is dramatically increased by exposure to ionising radiation. When such breaks take place, they are usually repaired accurately by DNA repair mechanisms within the cell. However, in a proportion of breaks, segments of DNA that are not normally contiguous will be joined (‘non-homologous end-joining’). If the joined fragments are from different chromosomes, this results in a translocation. If they are from the same chromosome, this will result in either inversion, duplication or deletion of a chromosomal fragment (Fig. 3.7).

Large insertions and deletions may be cytogenetically visible as chromosomal deletions or duplications. If the anomalies are too small to be detected by microscopy, they are termed microdeletions and microduplications. Many microdeletion syndromes have been described and most result from non-allelic homologous recombination between repeats of highly similar DNA sequences, which leads to recurrent chromosome anomalies – and clinical syndromes – occurring in unrelated individuals (Fig. 3.7 and Box 3.3).

Consequences of genomic variation

The consequence of an individual mutation depends on many factors, including the mutation type, the nature of the gene product and the position of the variant in the protein. Mutations can have profound or subtle effects on gene and cell function. Variations that have profound effects are responsible for ‘classical’ genetic diseases, whereas those with subtle effects may contribute to the pathogenesis of common disease where there is a genetic component, such as diabetes.
- Neutral variants have no effect on quality or type of protein produced.
- Loss-of-function mutations result in loss or reduction in the normal protein function. Whole-gene deletions are the archetypal loss-of-function variants but stop-gain or indel mutations (early in the ORF), missense mutations affecting a critical domain and splice-site mutations can also result in loss of protein function.

Genomics, health and disease

• Single nucleotide polymorphism (SNP)

Polymorphisms and common disease

Evolutionary selection

Gain-of-function mutations result in a gain of protein function. They are typically non-synonymous mutations that alter the protein structure, leading to activation/alteration of its normal function through causing either an interaction with a novel substrate or a change in its normal function.

Dominant negative mutations are the result of non-synonymous mutations or in-frame deletions/duplications but may also, less frequently, be caused by triplet repeat expansion mutations. Dominant negative mutations are heterozygous changes that result in the production of an abnormal protein that interferes with the normal functioning of the wild-type protein.

Normal genomic variation

We each have 5–50 million variants in our genome, occurring approximately every 300 bases. These variants are mostly polymorphisms, arising in more than 1% of the population; they have no or subtle effects on gene and cell function, and are not associated with a high risk of disease. Polymorphisms can occur within exons, introns or the intergenic regions that comprise 98–99% of the human genome. Each of the classes of genetic variant discussed on page 42 is present in the genome as a common polymorphism. However, the most frequent is the single nucleotide polymorphism, or SNP (pronounced ‘snip’), describing the substitution of a single base.

Polymorphisms and common disease

The protective and detrimental polymorphisms associated with common disease have been identified primarily through genome-wide association studies (GWAS, p. 56) and are the basis for many direct-to-consumer tests that purport to determine individual risk profiles for common diseases or traits such as cardiovascular disease, diabetes and even male-pattern baldness! An example is the polymorphism in the gene SLC2A9 that not only explains a significant proportion of the normal population variation in serum urate concentration but also predisposes ‘high-risk’ allele carriers to the development of gout. However, the current reality is that, until we have a more comprehensive understanding of the full genomic landscape and knowledge of the complete set of detrimental and protective polymorphisms, we cannot accurately assess risk.

Evolutionary selection

Genetic variants play an important role in evolutionary selection, with advantageous variants resulting in positive selection via improved reproductive fitness, and variations that decrease
reproductive fitness becoming excluded through evolution. Given this simple paradigm, it would be tempting to assume that common mutations are all advantageous and all rare mutations are pathogenic. Unfortunately, it is often difficult to classify any common mutation as either advantageous or deleterious – or, indeed, neutral. Mutations that are advantageous in early life and thus enhance reproductive fitness may be deleterious in later life. There may be mutations that are advantageous for survival in particular conditions (e.g. famine or pandemic) that may be disadvantageous in more benign circumstances by causing a predisposition to obesity or autoimmune disorders.

### Constitutional genetic disease

Familial genetic disease is caused by constitutional mutations, which are inherited through the germ line. However, different mutations in the same gene can have different consequences, depending on the genetic mechanism underlying that disease. About 1% of the human population carries constitutional mutations that cause disease.

### Constructing a family tree

The family tree – or pedigree – is a fundamental tool of the clinical geneticist, who will routinely take a three-generation family history, on both sides of the family, enquiring about details of all medical conditions in family members, consanguinity, dates of birth and death, and any history of pregnancy loss or infant death. The basic symbols and nomenclature used in drawing a pedigree are shown in Figure 3.8.

#### Patterns of disease inheritance

**Autosomal dominant inheritance**

Take some time to draw out the following pedigree:

Anne is referred to Clinical Genetics to discuss her personal history of colon cancer (she was diagnosed at the age of 46 years) and family history of colon/endometrial cancer: her mother was diagnosed with endometrial cancer at the age of 60 years and her cousin through her healthy maternal aunt was diagnosed with colon cancer in her fifties. Both her maternal grandmother and grandfather died of ‘old age’. There is no family history of note on her father’s side of the family. He has one brother and both his parents died of old age, in their eighties. Anne has two healthy daughters, aged 12 and 14 years, and a healthy full sister.

This family history is typical of an autosomal dominant condition (Fig. 3.8): in this case, a colon/endometrial cancer susceptibility syndrome known as Lynch’s syndrome, associated with disruption of one of the mismatch repair genes: *MSH2*, *MSH6*, *MLH1* and *PMS2* (see p. 830 and Box 3.11, p. 57).

---

**Fig. 3.8** Drawing a pedigree and patterns of inheritance. **A** The main symbols used to represent pedigrees in diagrammatic form. **B** The main modes of disease inheritance (see text for details).
Features of an autosomal dominant pedigree include:

- There are affected individuals in each generation (unless the mutation has arisen de novo, i.e. for the first time in an affected individual). However, variable penetrance and expressivity can influence the number of affected individuals and the severity of disease in each generation. Penetration is defined as the proportion of individuals bearing a mutated allele who develop the disease phenotype. The mutation is said to be fully penetrant if all individuals who inherit a mutation develop the disease. Expressivity describes the level of severity of each aspect of the disease phenotype.

- Males and females are usually affected in roughly equal numbers (unless the clinical presentation of the condition is gender-specific, such as an inherited susceptibility to breast and/or ovarian cancer).

The offspring risk for an individual affected with an autosomal dominant condition is 1 in 2 (or 50%). This offspring risk is true for each pregnancy, since half the affected individual gametes (sperm or egg cells) will contain the affected chromosome/gene and half will contain the normal chromosome/gene.

There is a long list of autosomal dominant conditions, some of which are shown in Box 3.4.

**Autosomal recessive inheritance**

As above, take some time to draw a pedigree representing the following:

Mr and Mrs Kent, a non-consanguineous couple, are referred because their son, Jamie, had severe neonatal liver disease. Included among the many investigations that the paediatric hepatologist undertook was testing for α₁-antitrypsin deficiency (Fig. 3.8). Jamie was shown to have the PIZZ phenotype. Testing confirmed both parents as carriers with PiMZ phenotypes. In the family, Jamie has an older sister who has no medical problems. Mr Kent is one of four children with two brothers and a sister and Mrs Kent has a younger brother. Both sets of grandparents are alive and well. There is no family history of α₁-antitrypsin deficiency.

This family history is characteristic of an autosomal recessive disorder (Fig. 3.8), where both alleles of a gene must be mutated before the disease is manifest in an individual; an affected individual inherits one mutant allele from each of their parents, who are therefore healthy carriers for the condition. An autosomal recessive condition might be suspected in a family where:

- Males and females are affected in roughly equal proportions.
- Parents are blood related; this is known as consanguinity.
- Where there is consanguinity, the mutations are usually homozygous, i.e. the same mutant allele is inherited from both parents.

---

**3.5 Alpha₁-antitrypsin deficiency**

**Inheritance pattern**
- Autosomal recessive

**Genetic cause**

**Prevalence**
- 1 in 1500–3000 of European ancestry

**Clinical presentation**
- Variable presentation from neonatal period through to adulthood
- Neonatal period: prolonged jaundice with conjugated hyperbilirubinaemia or (rarely) liver disease
- Adulthood: pulmonary emphysema and/or cirrhosis. Rarely, the skin disease, panniculitis, develops

**Disease mechanism**
- SERPINA1 encodes α₁-antitrypsin, which protects the body from the effects of neutrophil elastase. The symptoms of α₁-antitrypsin deficiency result from the effects of this enzyme attacking normal tissue

**Disease variants**
- M variant: if an individual has normal SERPINA1 genes and produces normal levels of α₁-antitrypsin, they are said to have an M variant
- S variant: p.Glu264Val mutation results in α₁-antitrypsin levels reduced to about 40% of normal
- Z variant: p.Glu342Lys mutation results in very little α₁-antitrypsin
- PIZZ: individuals who are homozygous for the p.Glu342Lys mutation are likely to have α₁-antitrypsin deficiency and the associated symptoms
- PIIZS: individuals who are compound heterozygous for p.Glu342Lys and p.Glu264Val are likely to be affected, especially if they smoke, but usually to a milder degree

---

**3.6 Duchenne muscular dystrophy**

**Inheritance pattern**
- X-linked recessive

**Genetic cause**
- Mutations or deletions encompassing/within the DMD (dystrophin) gene located at Xp21

**Prevalence**
- 1 in 3000–4000 live male births

**Clinical presentation**
- Delayed motor milestones
- Speech delay
- Grossly elevated creatine kinase (CK) levels (in the thousands)
- Ambulation is usually lost between the ages of 7 and 13 years
- Lifespan is reduced with a mean age of death, usually from respiratory failure, in the mid-twenties
- Cardiomyopathy affects almost all boys with Duchenne muscular dystrophy and some female carriers

**Disease mechanism**
- DMD encodes dystrophin, a major structural component of muscle
- Dystrophin links the internal cytoskeleton to the extracellular matrix

**Disease variants**
- Becker muscular dystrophy, although a separate disease, is also caused by mutations in the dystrophin gene
- In Duchenne muscular dystrophy, there is no dystrophin protein, whereas in Becker muscular dystrophy there is a reduction in the amount or alteration in the size of the dystrophin protein

*See also page 1143.*
have only one X chromosome, whereas females have two (see Fig. 3.1). However, occasionally, female carriers may exhibit signs of an X-linked disease due to a phenomenon called skewed X-inactivation. All female embryos, at about 100 cells in size, stably inactivate one of their two X chromosomes in each cell. Where this inactivation is random, approximately 50% of the cells will express the genes from one X chromosome and 50% of cells will express genes from the other. Where there is a mutant gene, there is often skewing away from the associated X chromosome, resulting in an unaffected female carrier. However, if, by chance, there is a disproportionate inactivation of the normal X chromosome with skewing towards the mutant allele, then an affected female carrier may be affected (albeit more mildly than males).

- The gene can be transmitted from female carriers to their sons: in families with an X-linked recessive condition, there are often a number of affected males related through unaffected females.

- Affected males cannot transmit the condition to their sons (but all their daughters would be carriers).

The risk of a female carrier having an affected child is 25% or half of her male offspring.

**Mitochondrial inheritance**

The mitochondrion is the main site of energy production within the cell. Mitochondria arose during evolution via the symbiotic association with an intracellular bacterium. They have a distinctive structure with functionally distinct inner and outer membranes. Mitochondria produce energy in the form of adenosine triphosphate (ATP), ATP is mostly derived from the metabolism of glucose and fat (Fig. 3.9). Glucose cannot enter mitochondria directly but is first metabolised to pyruvate via glycolysis. Pyruvate is then imported into the mitochondrion and metabolised to acetyl-co-enzyme A (acetyl-CoA). Fatty acids are transported into the mitochondria following conjugation with carnitine and are sequentially catabolised by a process called β-oxidation to produce acetyl-CoA. The acetyl-CoA from both pyruvate and fatty acid oxidation is used in the citric acid (Krebs) cycle – a series of enzymatic reactions that produces CO₂, the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavine adenine dinucleotide (FADH₂). Both NADH and FADH₂ then donate electrons to the respiratory chain. Here these elections are transferred via a complex series of reactions, resulting in the formation of a proton gradient across the inner mitochondrial membrane. The gradient is used by an inner mitochondrial membrane protein, ATP synthase, to produce ATP, which is then transported to other parts of the cell. Dephosphorylation of ATP is used to produce the energy required for many cellular processes.

Each mitochondrion contains 2–10 copies of a 16-kilobase (kb) double-stranded circular DNA molecule (mtDNA). This mtDNA contains 13 protein-coding genes, all involved in the respiratory chain, and the ncRNA genes required for protein synthesis within the mitochondria (Fig. 3.9). The mutational rate of mtDNA is relatively high due to the lack of protection by chromatin. Several mtDNA diseases characterised by defects in ATP production have been described. Mitochondria are most numerous in cells with high metabolic demands, such as muscle, retina and the basal ganglia, and these tissues tend to be the ones most severely affected in mitochondrial diseases (Box 3.7). There are many other mitochondrial diseases that are caused by mutations in nuclear genes, which encode proteins that are then imported into the mitochondrion and are critical for energy production, e.g. most forms of Leigh’s syndrome (although Leigh’s syndrome may also be caused by a mitochondrial gene mutation).

The inheritance of mtDNA disorders is characterised by transmission from females, but males and females generally are equally affected (see Fig. 3.8). Unlike the other inheritance patterns mentioned above, mitochondrial inheritance has nothing to do with meiosis but reflects the fact that mitochondrial DNA is transmitted by oocytes: sperm do not contribute mitochondria to the zygote. Mitochondrial disorders tend to be variable in penetrance and expressivity within families, and this is mostly accounted for by the fact that only a proportion of multiple mtDNA molecules within mitochondria contain the causal mutation (the degree of mtDNA heteroplasmy).

**Imprinting**

Several chromosomal regions (loci) have been identified where gene expression is inherited in a parent-of-origin-specific manner;

Somatic genetic disease

Somatic mutations are not inherited but instead occur during post-zygotic mitotic cell divisions at any point from embryonic development to late adult life. An example of this phenomenon is polyostotic fibrous dysplasia (McCune–Albright syndrome), in which somatic mutations lead to the development of fibrous tumors in multiple bones. These mutations are not passed on to offspring, as they are not present in the germ line.
which a somatic mutation in the $G_S$ alpha gene causes constitutive activation of downstream signalling, resulting in focal lesions in the skeleton and endocrine dysfunction (p. 1055).

The most important example of human disease caused by somatic mutations is cancer (see Ch. 33). Here, “driver” mutations occur within genes that are involved in regulating cell division or apoptosis, resulting in abnormal cell growth and tumour formation. The two general categories of cancer-causing mutation are gain-of-function mutations in growth-promoting genes (oncogenes) and loss-of-function mutations in growth-suppressing genes (tumour suppressor genes). Whichever mechanism is acting, most tumours require an initiating mutation in a single cell that can then escape from normal growth controls. This cell replicates more frequently or fails to undergo programmed death, resulting in clonal expansion. As the size of the clone increases, one or more cells may acquire additional mutations that confer a further growth advantage, leading to proliferation of these subclones, which may ultimately result in aggressive metastatic cancer.

The cell’s complex self-regulating machinery means that more than one mutation is usually required to produce a malignant tumour (see Fig. 33.3, p. 1318). For example, if a mutation results in activation of a growth factor gene or receptor, then that cell will replicate more frequently as a result of autocrine stimulation. However, this mutant cell will still be subject to normal cell-cycle checkpoints to promote DNA integrity in its progeny. If additional mutations in the same cell result in defective cell-cycle checkpoints, however, it will rapidly accumulate further mutations, which may allow completely unregulated growth and/or separation from its matrix and cellular attachments and/or resistance to apoptosis. As cell growth becomes increasingly disregulated, cells de-differentiate, lose their response to normal tissue environment and cease to ensure appropriate mitotic chromosomal segregation. These processes combine to generate the classical malignant characteristics of disorganised growth, variable levels of differentiation, and numerical and structural chromosome abnormalities. An increase in somatic mutation rate can occur on exposure to external mutagens, such as ultraviolet light or cigarette smoke, or if the cell has defects in DNA repair systems. Cancer is thus a disease that affects the fundamental processes of molecular and cell biology.

### Interrogating the genome: the changing landscape of genomic technologies

The analysis of metaphase chromosomes by light microscopy was the mainstay of clinical cytogenetic analysis for decades, the aim being to detect gain or loss of whole chromosomes (aneuploidy) or large chromosomal segments (>4 million bp). More recently, genome-wide microarrays (array comparative genomic hybridisation or array CGH) have replaced chromosome analysis, allowing rapid and precise detection of segmental gain or loss of DNA throughout the genome (see Box 3.3). Microarrays consist of grids of multiple wells containing short DNA sequences (reference DNA) that are complementary to known sequences in the genome. Patient and reference DNA are each labelled with a coloured fluorescent dye (generally, patient DNA is labelled with a green fluorescent dye and reference DNA with a red fluorescent dye) and added to the microarray grid. Where there is an equal quantity of patient and reference DNA bound to the spot, this results in yellow fluorescence. Where there is too much patient DNA (representing a duplication of a chromosome region), the spot will be greener; it will be more red (appears orange) where there is 2 : 1 ratio of the control:patient DNA (representing heterozygous deletion of a chromosome region; Fig. 3.10).

Array CGH and other array-based approaches can detect small chromosomal deletions and duplications. They are also generally more sensitive than conventional karyotyping at detecting mosaicism (where there are two or more populations of cells, derived from a single fertilised egg, with different genotypes).

primers designed to anneal to a specific genomic region. This as a template during the subsequent replication step, guided by cooling allow the initial separation of double-stranded DNA into method utilises thermal cycling: repeated cycles of heating and for further analyses – most commonly, DNA sequencing. The polymerase chain reaction (PCR) is a fundamental laboratory For instance, if, through the array CGH investigation for an of a phenotype or risk unrelated to the presenting complaint. duplication encompassing a gene or genes that are causative neurosusceptibility loci. stochastic) must influence the phenotypic expression of these disorder than in the general population. The current understanding individuals with a learning disability and/or autistic spectrum penetrance are therefore identified at greater frequencies among CNVs of variable penetrance and incidental findings. A CNV of uncertain clinical significance describes a deletion or gain of chromosome material where there are insufficient data to conclude whether or not it is associated with a learning disability and/or medical problems. While this uncertainty can be difficult to prepare families for and can be associated with considerable anxiety, it is likely that there will be greater clarity in the future as we generate larger CNV datasets. A CNV of variable penetrance, also known as a neurosusceptibility locus, describes a chromosome deletion or duplication associated with a lower threshold for manifesting a learning disability or autistic spectrum disorder. CNVs of variable penetrance are therefore identified at greater frequencies among individuals with a learning disability and/or autistic spectrum disorder than in the general population. The current understanding is that additional modifying factors (genetic, environmental or stochastic) must influence the phenotypic expression of these neurosusceptibility loci. Finally, an incidental CNV finding describes a deletion or duplication encompassing a gene or genes that are causative of a phenotype or risk unrelated to the presenting complaint. For instance, if, through the array CGH investigation for an intellectual disability, a deletion encompassing the BRCA1 gene were identified, this would be considered an incidental finding.

However, array-based approaches will not detect balanced chromosome rearrangements where there is no loss or gain of genes/chromosome material, such as balanced reciprocal translocations, or a global increase in copy number, such as triploidy. The widespread use of array-based approaches has brought a number of challenges for clinical interpretation, including the identification of copy number variants (CNVs) of uncertain clinical significance, CNVs of variable penetrance and incidental findings. A CNV of uncertain clinical significance describes a loss or gain of chromosome material where there are insufficient data to conclude whether or not it is associated with a learning disability and/or medical problems. While this uncertainty can be difficult to prepare families for and can be associated with considerable anxiety, it is likely that there will be greater clarity in the future as we generate larger CNV datasets.

Looking at genes

Gene amplification: polymererase chain reaction

The polymerase chain reaction (PCR) is a fundamental laboratory technique that amplifies targeted sections of the human genome for further analyses – most commonly, DNA sequencing. The method utilises thermal cycling: repeated cycles of heating and cooling allow the initial separation of double-stranded DNA into two single strands (known as denaturation), each of which serves as a template during the subsequent replication step, guided by primers designed to anneal to a specific genomic region. This cycle of heating/cooling and denaturation/replication is repeated many times, resulting in the exponential amplification of DNA between primer sites (Fig. 3.11).

Gene sequencing

In the mid-1970s, a scientist called Fred Sanger pioneered a DNA sequencing technique (‘Sanger sequencing’) that determined the precise order and nucleotide type (thymine, cytosine, adenine and guanine) in a molecule of DNA. Modern Sanger sequencing uses fluorescently labelled, chain-terminating nucleotides that are sequentially incorporated into the newly synthesised DNA, generating multiple DNA chains of differing lengths. These DNA chains are subject to capillary electrophoresis, which separates them by size, allowing the fragments to be ‘read’ by a laser and producing a sequence chromatogram that corresponds to the target sequence (Fig. 3.12). Although transformative, Sanger sequencing was difficult and costly to scale, as exemplified by the Human Genome Project, which took 12 years to sequence the entire human genome at a cost approaching 3 billion dollars. Recently, DNA sequencing has been transformed again by a group of technologies collectively known as ‘next-generation sequencing’ (NGS; Fig. 3.13). This refers to a family of post-Sanger sequencing technologies that utilise the same five basic principles:

- **Library preparation**: DNA samples are fragmented (by enzyme cleavage or ultrasound) and then modified with a custom adapter sequence.
- **Amplification**: the library fragment is amplified to produce DNA clusters, each originating from a single DNA fragment. Each cluster will act as a single sequencing reaction.
- **Capture**: if an entire genome is being sequenced, this step will not be included. The capture step is required if targeted resequencing is necessary, such as for a panel gene test or an exome (Box 3.9).
- **Sequencing**: each DNA cluster is simultaneously sequenced and the data from each captured; this is known as a ‘read’ and is usually between 50 and 300 bases long sequenced (see Box 3.10 for a detailed description of the three most commonly used sequencing methods: synthesis, ligation and ion semiconductor sequencing).
- **Alignment and variant identification**: specialised software analyses read sequences and compares the data to a reference template. This is known as ‘alignment’ or ‘mapping’ and, although there are 3 billion bases in the
Interrogating the genome: the changing landscape of genomic technologies

• Human genome, allows the remarkably accurate determination of the genomic origin where a read consists of 25 nucleotides or more. Variants are identified as differences between the read and the reference genome. For instance, if there is a different nucleotide in half the reads at a given position compared to the reference genome, this is likely to represent a heterozygous base substitution. The number of reads that align at a given point is called the ‘depth’ or ‘coverage’. The higher the read depth, the more accurate the variant call. However, in general, a depth of 30 or more reads is generally accepted as producing diagnostic-grade results.

Rather than sequencing only one small section of DNA at a time, NGS allows the analysis of many hundreds of thousands of DNA strands in a single experiment and so is also commonly referred to as multiple parallel sequencing technology. Today’s NGS machines can sequence the entire human genome in a single day at a cost approaching 1000 US dollars.

**NGS capture**

Although we now have the capability to sequence the entire genome in a single experiment, whole-genome sequencing is not always the optimal use of NGS. NGS capture refers to the ‘pull-down’ of a targeted region of the genome and may constitute several to several hundred genes associated with a given phenotype (a gene panel), the exons of all known coding genes (an exome), or the exons of all coding genes known to be associated with disease (a clinical exome). Each of these targeted resequencing approaches is associated with a number of advantages and disadvantages (see Box 3.9). In order for NGS to be used for optimal patient benefit, it is essential for the clinician to have a good understanding of which test is the best one to request in any given clinical presentation.

**Challenges of NGS technologies**

Genomic technologies have the potential to transform the way that we practise medicine, and ever faster and cheaper DNA sequencing offers increasing opportunities to prevent, diagnose and treat disease. However, genomic technologies are not without their challenges: for instance, storing the enormous quantities of data generated by NGS. While the A, C, T and G of our genomic code could be stored on the memory of a smartphone, huge computers, able to store several petabytes of data (where 1 petabyte is 1 million gigabytes of data), are required to store the information needed to generate each individual’s genome.

Even if we can store and handle these huge datasets successfully, we then need to be able to sift through the millions of...
normal variants to identify the single (or, rarely, several) pathogenic, disease-causing mutation. While this can, to an extent, be achieved through the application of complex algorithms, these take time and considerable expertise to develop and are not infallible.

Furthermore, even after these data have been sifted by bioinformaticians, it is highly likely that clinicians will be left with some variants for which there are insufficient data to enable their definitive categorisation as either pathogenic or non-pathogenic. This may be because we simply do not know enough about the gene, because the particular variant has not previously been reported and/or it is identified in an unaffected parent. These variants must be interpreted with caution and, more usually, their interpretation will require input from a genetics expert in the context of the clinical presentation, where an ‘innocent until proven guilty’ approach is often adopted.

Finally, if we are to interrogate the entire genome or even the exome, it is foreseeable that we will routinely identify ‘incidental’ or secondary findings – in other words, findings not related to the initial diagnostic question. The UK has so far advocated a conservative approach to incidental findings.

**Uses of NGS**

NGS is now frequently used, within diagnostic laboratories, to identify base substitutions and indels (although the latter were
Interrogating the genome: the changing landscape of genomic technologies

3.10 Next-generation sequencing methods

Sequencing by synthesis (Fig. 3.13)
- The most frequently used NGS method
- Used in Illumina systems (commonly used in diagnostic laboratories)
- Uses fluorescently labelled, terminator nucleotides that are sequentially incorporated into a growing DNA chain
- Library DNA samples (fragmented DNA flanked by DNA adapter sequences) are anchored to a flow cell by hybridisation of the DNA adapter sequence to probes on the flow-cell surface
- Amplification occurs by washing the flow cell in a mixture containing all four fluorescently labelled terminator nucleotides: A, C, T and G
- Once the nucleotide, complementary to the first base of the DNA template, is incorporated, no further nucleotides can be added until the mixture is washed away
- The nucleotide terminator is shed and the newly incorporated nucleotide reverts to a regular, non-fluorescent nucleotide that can be extended
- The process is then repeated with the incorporation of a second base etc.
- Sequencing by synthesis is therefore space- and time-dependent: a sensor will detect the order of fluorescent emissions for each spot on the plate (representing the cluster) and determine the sequence for that read

Sequencing by ligation
- Used in SOLiD systems
- Uses DNA ligase rather than DNA polymerase (as is used in sequencing by synthesis) and short oligonucleotides (as opposed to single nucleotides)
- Library DNA samples are washed in a mixture containing oligonucleotide probes representing 4–16 dinucleotide sequences. Only one nucleotide in the probe is fluorescently labelled
- The complementary oligo probes will hybridise, using DNA ligase, to the target sequence, initially at a primer annealed to the anchor site and then progressively along the DNA strand
- After incorporation of each probe, fluorescence is measured and the dye is cleaved off
- Eventually, a new strand is synthesised (composed of a series of the oligo probes)
- A new strand is then synthesised but is offset by one nucleotide
- The process is repeated a number of times (5 rounds in the SOLiD system), providing overlapping templates that are analysed and a composite of the target sequence determined

Ion semiconductor sequencing
- When a nucleotide is incorporated into a growing DNA strand, a hydrogen ion is released that can be detected by an alteration in the pH of the solution. This hydrogen ion release forms the basis of ion semiconductor sequencing
- Each amplified DNA cluster is located above a semiconductor transistor, capable of detecting differences in the pH of the solution
- The DNA cluster is washed in a mixture containing only one type of nucleotide
- If the correct nucleotide, complementary to the next base on the DNA template, is in the mixture and incorporated, a hydrogen ion is released and detected
- If a homopolymer (sequence of two or more identical nucleotides) is present, this will be detected as a decrease in pH proportionate to the number of identical nucleotides in the sequence

NGS is still not able to interrogate the epigenome (and so will not identify conditions caused by a disruption of imprinting, such as Beckwith–Wiedemann, Silver–Russell, Angelman’s and Prader–Willi syndromes) and will not detect triplet repeat expansions such as those that cause Huntington’s disease.

---

Fig. 3.13 Sequencing by synthesis as used in the Illumina system.
(1) Library preparation: DNA is fragmented and specialist adapters are ligated to the fragmented ends. (2) Cluster amplification: the library is loaded to a flow cell and the adapters hybridise to the flow-cell surface. Each bound fragment is hybridised. (3) Sequencing. (4) Alignment and variant interpretation: reads are aligned to a reference sequence using complex software and differences between reference and case genomes are identified.
myotonic dystrophy and fragile X syndrome (see Boxes 3.8 and 3.2).

### Third-generation sequencing

Increasingly, third-generation or single-molecule sequencing is entering the diagnostic arena. As with next- or second-generation sequencing, a number of different platforms are commercially available. One of the most successful is SMRT technology (single-molecule sequencing in real time), developed by Pacific Biosciences. This system utilizes a single-stranded DNA molecule (as compared to the amplified clusters used in NGS), which acts as a template for the sequential incorporation, using a polymerase, of fluorescently labelled nucleotides. As each complementary nucleotide is added, the fluorescence (and therefore the identity of the nucleotide) is recorded before it is removed and another nucleotide is added.

A key advantage of third-generation sequencing is the long length of the read it generates: in the region of 10–15 kilobases. It is also cheaper than NGS, as fewer reagents are required. Given these inherent advantages, third-generation sequencing is likely to supersede NGS in the near future. Given the confusion surrounding the terminology of NGS and third-generation sequencing, these technologies are increasingly referred to as ‘massively parallel sequencing’.

### Genomics and clinical practice

#### Genomics and health care

### Genomics in rare neurodevelopmental disorders

Although, by definition, the diagnosis of a rare disorder is made infrequently, rare diseases, when considered together, affect about 3 million people in the UK, the majority of whom are children. NGS has transformed the ability to diagnose individuals affected by a rare disease. Whereas previously, when we were restricted to the sequential analysis of single genes, a clinician would need to make a clinical diagnosis in order to target testing, NGS allows the interrogation of multiple genes in a single experiment. This might be done through a gene panel, a clinical exome or an exome (see Box 3.9 and p. 53), and has increased the diagnostic yield in neurodevelopmental disorders to approximately 30%. Not only does the identification of the genetic cause of a rare disorder potentially provide families with answers, prognostic information and the opportunity to meet and derive support from other affected families but also it can provide valuable information for those couples planning further children and wishing to consider prenatal testing in the future.

### Genomics and common disease

Most common disorders are determined by interactions between a number of genes and the environment. In this situation, the genetic contribution to disease is termed polygenic. Until recently, very little progress had been made in identifying the genetic variants that predispose to common disorders, but this has been changed by the advent of genome-wide association studies. A GWAS typically involves genotyping many (> 500,000) genetic markers (SNPs) spread across the genome in a large group of individuals with the disease and in controls. By comparing the SNP genotypes in cases and controls, it is possible to identify regions of the genome, and therefore genes, more strongly associated with a given SNP profile and therefore more likely to contribute to the disease under study.

### Genomics and obstetrics

Prenatal genetic testing may be performed where a pregnancy is considered at increased risk of being affected with a genetic condition, either because of the ultrasound/biochemical screening results or because of the family history. While invasive tests, such as amniocentesis and chorionic villus sampling, have been the mainstay of prenatal diagnosis for many years, they are increasingly being superseded by non-invasive testing of cell-free fetal DNA (cffDNA), originating from placental trophoblasts and detectable in the maternal circulation from 4–5 weeks’ gestation; it is present in sufficient quantities for testing by 9 weeks.

- **Non-invasive prenatal testing (NIPT):** the sequencing and quantification, using NGS, of cffDNA chromosome-specific DNA sequences to identify trisomy 13, 18 or 21. The accuracy of NIPT in detecting pregnancy-specific aneuploidy approaches 98%. A false-negative result can occur when there is too little cffDNA (possibly due to early gestation or high maternal body mass index) or when aneuploidy has arisen later in development and is confined to the embryo and not represented in the placenta. False positives can occur with confined placental mosaicism (describing aneuploidy in the placenta, not the fetus) or with an alternative cause of aneuploidy in the maternal circulation, such as a cell-free tumour DNA.

- **Non-invasive prenatal diagnosis (NIPD):** the identification of a fetal single-gene defect that either has been paternally inherited or has arisen de novo and so is not identifiable in the maternal genome. Examples of conditions that are currently amenable to NIPD include achondroplasia and the craniosynostoses. Increasingly, however, NIPD is being used for autosomal recessive conditions such as cystic fibrosis, where parents are carriers for different mutations. The free fetal DNA is tested to see whether the paternal mutation is identified and, if absent, the fetus is not affected. If the paternal mutation is identified, however, a definitive invasive test is required to determine whether the maternal mutation has also been inherited and the fetus is affected.

Where a genetic diagnosis is known in a family, a couple may opt to undertake pre-implantation genetic diagnosis (PGD). PGD is used as an adjunct to in vitro fertilisation and involves the genetic testing of a single cell from a developing embryo, prior to implantation.

### Genomics and oncology

Until recently, individuals were stratified to genetic testing if they presented with a personal and/or family history suggestive of an inherited cancer predisposition syndrome (Box 3.11). Relevant clinical information included the age of cancer diagnosis and number/type of tumours. For example, the diagnosis of bilateral breast cancer in a woman in her thirties with a mother who had ovarian cancer in her forties is suggestive of BRCA1/2-associated familial breast/ovarian cancer. In many familial cancer syndromes, somatic mutations act together with an inherited mutation to cause specific cancers (p. 50). Familial cancer syndromes may be due to germ-line loss-of-function mutations in tumour suppressor genes encoding DNA repair enzymes or proto-oncogenes.

At the cellular level, loss of one copy of a tumour suppressor
ever) in some members of these cancer-prone families. In DNA repair diseases, the inherited mutations increase the somatic mutation rate. Autosomal dominant mutations in genes encoding components of specific DNA repair systems are relatively common causes of familial colon cancer and breast cancer (e.g. BRCA1).

Increasingly, genetics is moving into the mainstream, becoming integrated into routine oncological care as new gene-specific treatments are introduced. Testing for a genetic predisposition gene does not have any functional consequences, as the cell is protected by the remaining normal copy. However, a somatic mutation affecting the normal allele is likely to occur in one cell at some point during life, resulting in complete loss of tumour suppressor activity and a tumour developing by clonal expansion of that cell. This two-hit mechanism (one inherited, one somatic) for cancer development is known as the Knudson hypothesis. It explains why tumours may not develop for many years (or

to cancer is therefore moving from the domain of clinical genetics, where it has informed diagnosis, cascade treatment and screening/prophylactic management, to oncology, where it is informing the immediate management of the patient following cancer diagnosis. This is exemplified by BRCA1 and BRCA2 (BRCA1/2)-related breast cancer. Previously, women with a mutation in either the BRCA1 or BRCA2 gene would have received similar first-line chemotherapy to women with a sporadic breast cancer without a known genetic association. More recently, it has been shown that BRCA1/2 mutation-positive tumours are sensitive to poly ADP ribose polymerase (PARP) inhibitors. PARP inhibitors block the single-strand break-repair pathway. In a BRCA1/2 mutation-positive tumour – with compromised double-strand break repair – the additional loss of the single-strand break-repair pathway will drive the cell towards apoptosis. Indeed, PARP inhibitors have been shown to be so effective at destroying BRCA1/2 mutation-positive tumour cells, and with such minimal side-effects, that BRCA1/2 gene testing is increasingly determining patient management. It is likely, with a growing understanding of the genomic architecture of tumours, increasing accessibility of NGS and an expanding portfolio of gene-directed therapies, that testing for many of the other inherited cancer susceptibility genes will, in time, move into the mainstream.

**Genomics in infectious disease**

NGS technologies are also transforming infectious disease. Given that a microbial genome can be sequenced within a single day at a current cost of less than 100 US dollars, microbiologists are able to identify a causative microorganism and target effective treatment rapidly and accurately. Moreover, microbial genome sequencing enables the effective surveillance of infections to reduce and prevent transmission. Finally, an understanding of the microbial genome will drive the development of vaccines and antibiotics, essential in an era characterised by increasing microbial resistance to established antibiotic agents.

**Treatment of genetic disease**

**Pharmacogenomics**

Pharmacogenomics is the science of dissecting the genetic determinants of drug kinetics and effects using information from the human genome. For more than 50 years, it has been appreciated that polymorphic mutations within genes can affect individual responses to some drugs, such as loss-of-function mutations in CYP2D6 that cause hypersensitivity to debrisoquine, an adrenergic-blocking medication formerly used for the treatment of hypertension, in 3% of the population. This gene is part of a large family of highly polymorphic genes encoding cytochrome P450 proteins, mostly expressed in the liver, which determine the metabolism of a host of specific drugs. Polymorphisms in the CYP2D6 gene also determine codeine activation, while those in the CYP2C9 gene affect warfarin inactivation. Polymorphisms in these and other drug metabolic genes determine the persistence of drugs and, therefore, should provide information about dosages and toxicity. With the increasing use of NGS, genetic testing for assessment of drug response is seldom employed routinely, but in the future it may be possible to predict the best specific drugs and dosages for individual patients based on genetic profiling: so-called ‘personalised medicine’. An example is the enzyme thiopurine methyltransferase (TPMT), which catabolises azathioprine, a drug that is used in the treatment of autoimmune diseases and in cancer chemotherapy. Genetic screening for polymorphic variants of TPMT can be useful in identifying patients who have increased sensitivity to the effects of azathioprine and who can be treated with lower doses than normal.

**Gene therapy and genome editing**

Replacing or repairing mutated genes (gene therapy) is challenging in humans. Retroviral-mediated ex vivo replacement of the defective gene in bone marrow cells for the treatment of severe combined immune deficiency syndrome (p. 79) has been successful. The major problems with clinical use of virally delivered gene therapy have been oncogenic integration of the exogenous DNA into the genome and severe immune response to the virus.

Other therapies for genetic disease include PTC124, a compound that can ‘force’ cells to read through a mutation that results in a premature termination codon in an ORF with the aim of producing a near-normal protein product. This therapeutic approach could be applied to any genetic disease caused by nonsense mutations.

The most exciting development in genetics for a generation has been the discovery of accurate, efficient and specific techniques to enable editing of the genome in cells and organisms. This technology is known as CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats and CRISPR-associated) genome editing. It is likely that ex vivo correction of genetic disease will become commonplace over the next few years. In vivo correction is not yet possible and will take much longer to become part of clinical practice.

**Induced pluripotent stem cells and regenerative medicine**

Adult stem-cell therapy has been in wide use for decades in the form of bone marrow transplantation. The identification of adult stem cells for other tissues, coupled with the ability to purify and maintain such cells in vitro, now offers exciting therapeutic potential for other diseases. It was recently discovered that many different adult cell types can be trans-differentiated to form cells (induced pluripotent stem cells or IPS cells) with almost all the characteristics of embryonal stem cells derived from the early blastocyst. In mammalian model species, such cells can be taken and used to regenerate differentiated tissue cells, such as in heart and brain. They have great potential both for the development of tissue models of human disease and for regenerative medicine.

**Pathway medicine**

The ability to manipulate pathways that have been altered in genetic disease has tremendous therapeutic potential for Mendelian disease, but a firm understanding of both disease pathogenesis and drug action at a biochemical level is required. An exciting example has been the discovery that the vascular pathology associated with Marfan’s syndrome is due to the defective fibrillin molecules causing up-regulation of transforming growth factor (TGF)-β signalling in the vessel wall. Losartan is an antihypertensive drug that is marketed as an angiotensin II receptor antagonist. However, it also acts as a partial antagonist of TGF-β signalling and is effective in preventing aortic dilatation in a mouse model of Marfan’s syndrome, showing promising effects in early human clinical trials.
Ethics in a genomic age

As genomic technology is increasingly moving into mainstream clinical practice, it is essential for clinicians from all specialties to appreciate the complexities of genetic testing and consider whether genetic testing is the right thing to do in a given clinical scenario. To exemplify the ethical considerations associated with genetic testing, it may be helpful to think about them in the context of a clinical scenario. As you read the scenario, try to think what counselling/ethical issues might arise.

A 32-year-old woman is referred to discuss BRCA2 testing; she is currently pregnant with her second child (she already has a 2-year-old daughter) and has an identical twin sister. Her mother, a healthy 65-year-old with Ashkenazi Jewish ancestry, participated in direct-to-consumer testing (DCT) for ‘a bit of fun’ and a BRCA2 mutation – common in the Ashkenazi Jewish population – was identified. There is no significant cancer family history of note.

Consider the following issues:

- **Pre-symptomatic/predictive testing:** this describes testing for a known familial gene mutation in an unaffected individual (compared with diagnostic testing, where genetic testing is undertaken in an affected individual). Although this could be considered for the unaffected patient, in the current scenario any testing would also have implications for her identical twin sister. This needs to be fully explored with the patient and her sister prior to testing. There is also the potential issue of predictive testing in the patient’s first child. A fundamental tenet in clinical genetics is that predictive genetic testing should be avoided in childhood for adult-onset conditions. This is because, if no benefit to the patient is accrued through childhood testing, it is better to retain the child’s right to decide for herself, when she is old enough, whether she wishes to participate in genetic testing or not.

- **Prenatal testing:** the principles behind predictive genetic testing in childhood can be extended to prenatal testing, i.e. if a pregnancy is being continued, a baby should not be tested for an adult-onset condition that cannot be prevented or treated in childhood. However, prenatal testing itself is hugely controversial and there is much debate as to how severe a condition should be to justify prenatal diagnosis, which would determine ongoing pregnancy decisions.

- **DCT:** while DCT can be interesting and empowering for individuals wishing to find out more about their genetic backgrounds, it also has several drawbacks. Perhaps the main one is that, unlike face-to-face genetic counselling (which usually precedes any genetic testing, certainly where there are serious health implications for the individual and their family, such as is associated with BRCA1/2 mutations), DCT is undertaken in isolation with no direct access to professional support. Furthermore, in addition to some (common) single-gene mutations, such as the founder BRCA1/2 mutations frequently identified in the Ashkenazi Jewish population and discussed in this example, current DCT packages utilise a series of SNPs to determine an overall risk profile; they evaluate the number of detrimental and protective SNPs for a given disease. However, given that only a minority of the risk SNPs have so far been characterised, this is often inaccurate. Individuals may be falsely reassured that they are not at increased risk of a genetic condition despite a family history suggesting otherwise, resulting in inadequate surveillance and/or management.

The ethical considerations listed in this clinical scenario give just a flavour of some of the issues frequently encountered in clinical genetics. They are not meant to be an exhaustive summary and whole textbooks and meetings are devoted to the discussion of hugely complex ethical issues in genetics. However, a guiding principle is that, although each counselling situation will be unique with specific communication and ethical challenges, a genetic result is permanent and has implications for the whole family, not just the individual. Where possible, therefore, an informed decision regarding genetic testing should be taken by a competent adult following counselling by an experienced and appropriately trained clinician.

The immune system has evolved to identify and destroy pathogens while minimising damage to host tissue. Despite the ancient observation that recovery from an infectious disease frequently results in protection against that condition, the existence of the immune system as a functional entity was not recognised until the end of the 19th century. More recently, it has become clear that the immune system not only protects against infection but also regulates tissue repair following injury, and when dysregulated, governs the responses that can lead to autoimmune and auto-inflammatory diseases. Dysfunction or deficiency of the immune response can lead to a wide variety of diseases that may potentially involve every organ system in the body.

The aim of this chapter is to provide a general understanding of the immune system, how it contributes to human disease and how manipulation of the immune system can be put to therapeutic use. A review of the key components of the immune response is followed by sections that illustrate the clinical presentation of the most common forms of immune dysfunction: immune deficiency, inflammation, autoimmunity and allergy. More detailed discussion of individual conditions can be found in the relevant organ-specific chapters of this book.

**Functional anatomy and physiology**

The immune system consists of an intricately linked network of lymphoid organs, cells and proteins that are strategically placed to protect against infection (Fig. 4.1). Immune defences are normally categorised into the innate immune response, which provides immediate protection against an invading pathogen, and the adaptive or acquired immune response, which takes more time to develop but confers exquisite specificity and long-lasting protection.

**The innate immune system**

Innate defences against infection include anatomical barriers, phagocytic cells, soluble molecules such as complement and acute phase proteins, and natural killer cells. The innate immune system recognises generic microbial structures present on non-mammalian tissue and can be mobilised within minutes. A specific stimulus will elicit essentially identical responses in different individuals, in contrast with adaptive antibody and T-cell responses, which vary greatly between individuals.

**Physical barriers**

The tightly packed keratinised cells of the skin physically limit colonisation by microorganisms. The hydrophobic oils that are secreted by sebaceous glands further repel water and microorganisms, and microbial growth is inhibited by the skin’s low pH and low oxygen tension. Sweat also contains lysozyme, an enzyme that destroys the structural integrity of bacterial cell walls; ammonia, which has antibacterial properties; and several...
antimicrobial peptides such as defensins. Similarly, the mucous membranes of the respiratory, gastrointestinal and genitourinary tracts provide a physical barrier to infection. Secreted mucus traps invading pathogens, and immunoglobulin A (IgA), generated by the adaptive immune system, prevents bacteria and viruses attaching to and penetrating epithelial cells. As in the skin, lysozyme and antimicrobial peptides within mucosal membranes directly kill invading pathogens, and lactoferrin acts to starve invading bacteria of iron. Within the respiratory tract, cilia directly trap pathogens and contribute to removal of mucus, assisted by physical manoeuvres such as sneezing and coughing. In the gastrointestinal tract, hydrochloric acid and salivary amylase chemically destroy bacteria, while normal peristalsis and induced vomiting or diarrhoea assist clearance of invading organisms.

The microbiome, which is made up of endogenous commensal bacteria, provides an additional constitutive defence against infection. Approximately $10^{14}$ bacteria normally reside at epithelial surfaces in symbiosis with the human host (p. 102). They compete with pathogenic microorganisms for scarce resources, including space and nutrients, and produce fatty acids and bactericidins that inhibit the growth of many pathogens. In addition, recent research has demonstrated that commensal bacteria help to shape the immune response by inducing specific regulatory T cells within the intestine. Eradication of the normal flora with broad-spectrum antibiotics commonly results in opportunistic infection by organisms such as *Clostridium difficile*, which rapidly colonise an undefended ecological niche.

These constitutive barriers are highly effective, but if external defences are breached by a wound or pathogenic organism, the specific soluble proteins and cells of the innate immune system are activated.

### Phagocytes

Phagocytes (‘eating cells’) are specialised cells that ingest and kill microorganisms, scavenge cellular and infectious debris, and produce inflammatory molecules that regulate other components of the immune system. They include neutrophils, monocytes and macrophages, and are particularly important for defence against bacterial and fungal infections. Phagocytes express a wide range of surface receptors, including pattern recognition receptors (PRRs), which recognise pathogen-associated molecular patterns (PAMPs) on invading microorganisms, allowing their identification. The PRRs include Toll-like receptors, nucleotide oligomerisation domain (NOD) protein-like receptors and mannose receptors, whereas the PAMPs they recognise are molecular motifs not present on mammalian cells, including bacterial cell wall components, bacterial DNA and viral double-stranded RNA. While phagocytes can recognise microorganisms through PRRs alone, engulfment of microorganisms is greatly enhanced by opsonisation. Opsonins include acute phase proteins produced by the liver, such as C-reactive protein and complement. Antibodies generated by the adaptive immune system also act as opsonins. They bind both to the pathogen and to phagocyte receptors, acting as a bridge between the two to facilitate phagocytosis (Fig. 4.2). This is followed by intracellular pathogen destruction and downstream activation of pro-inflammatory genes, resulting in the generation of pro-inflammatory cytokines as discussed below.

![Fig. 4.2 Phagocytosis and opsonisation.](image)
Neutrophils

Neutrophils, also known as polymorphonuclear leucocytes, are derived from the bone marrow and circulate freely in the blood. They are short-lived cells with a half-life of 6 hours, and are produced at the rate of $10^{11}$ cells daily. Their functions are to kill microorganisms, to facilitate rapid transit of cells through tissues, and to amplify the immune response non-specifically. These functions are mediated by enzymes contained in granules, which also provide an intracellular milieu for the killing and degradation of microorganisms.

Two main types of granule are recognised: primary or azurophil granules, and the more numerous secondary or specific granules. Primary granules contain myeloperoxidase and other enzymes important for intracellular killing and digestion of ingested microbes. Secondary granules are smaller and contain lysozyme, collagenase and lactoferrin, which can be released into the extracellular space. Enzyme production is increased in response to infection, which is reflected by more intense granule staining on microscopy, known as ‘toxic granulation’.

Changes in damaged or infected cells trigger local production of inflammatory molecules and cytokines. These cytokines stimulate the production and maturation of neutrophils in the bone marrow, and their release into the circulation. Neutrophils are recruited to specific sites of infection by chemotactic agents, such as interleukin 8 (IL-8), and by activation of local endothelium. Up-regulation of cellular adhesion molecules on neutrophils and the endothelium also facilitates neutrophil migration. The transit of neutrophils through the blood stream is responsible for the rise in neutrophil count that occurs in early infection. Once present within infected tissue, activated neutrophils seek out and engulf invading microorganisms. These are initially enclosed within membrane-bound vesicles, which fuse with cytoplasmic granules to form the phagolysosome. Within this protected compartment, killing of the organism occurs through a combination of oxidative and non-oxidative killing. Oxidative killing, also known as the respiratory burst, is mediated by the nicotinamide adenine dinucleotide phosphate (NADPH)–oxidase enzyme complex, which converts oxygen into reactive oxygen species such as hydrogen peroxide and superoxide that are lethal to microorganisms. The myeloperoxidase enzyme within neutrophils produces hypochlorous acid, which is a powerful oxidant and antimicrobial agent. Non-oxidative (oxygen-independent) killing occurs through the release of bactericidal enzymes into the phagolysosome. Each enzyme has a distinct antimicrobial spectrum, providing broad coverage against bacteria and fungi.

An additional, recently identified form of neutrophil-mediated killing is neutrophil extracellular trap (NET) formation. Activated neutrophils can release chromatin with granule proteins such as elastase to form an extracellular matrix that binds to microbial proteins. This can immobilise or kill microorganisms without requiring phagocytosis. The process of phagocytosis and NET formation (NETosis) depletes neutrophil glycogen reserves and is followed by neutrophil death. As the cells die, their contents are released and lysosomal enzymes degrade collagen and other components of the interstitium, causing liquefaction of closely adjacent tissue. The accumulation of dead and dying neutrophils results in the formation of pus, which, if extensive, may lead to abscess formation.

Monocytes and macrophages

Monocytes are the precursors of tissue macrophages. They are produced in the bone marrow and enter the circulation, where they constitute about 5% of leucocytes. From the blood stream they migrate to peripheral tissues, where they differentiate into tissue macrophages and reside for long periods. Specialised populations of tissue macrophages include Kupffer cells in the liver, alveolar macrophages in the lung, mesangial cells in the kidney, and microglial cells in the brain. Macrophages, like neutrophils, are capable of phagocytosis and killing of microorganisms but also play an important role in the amplification and regulation of the inflammatory response (Box 4.1). They are particularly important in tissue surveillance and constantly survey their immediate surroundings for signs of tissue damage or invading organisms.

Dendritic cells

Dendritic cells are specialised antigen-presenting cells that are present in tissues in contact with the external environment, such as the skin and mucosal membranes. They can also be found in an immature state in the blood. They sample the environment for foreign particles and, once activated, carry microbial antigens to regional lymph nodes, where they interact with T cells and B cells to initiate and shape the adaptive immune response.

Cytokines

Cytokines are signalling proteins produced by cells of the immune system and a variety of other cell types. More than 100 have been identified. Cytokines have complex and overlapping roles in cellular communication and regulation of the immune response. Subtle differences in cytokine production, particularly at the initiation of an immune response, can have a major impact on outcome. Cytokines bind to specific receptors on target cells and activate downstream intracellular signalling pathways, ultimately leading to changes in gene transcription and cellular function. Two important signalling pathways are illustrated in Figure 4.3. The nuclear factor kappa B (NFκB) pathway is activated by tumour necrosis factor (TNF), by other members of the TNF superfamily such as receptor activator of nuclear kappa B ligand
IKK, which in turn leads to phosphorylation of the inhibitor of nuclear factor kappa B protein (IkB), causing it to be degraded, and allowing NFκB to translocate to the nucleus and activate gene transcription. The Janus kinase/signal transducer and activators of transcription (JAK-STAT) pathway is involved in the immune response. Cytokines regulate the immune response through binding to specific receptors that activate a variety of intracellular signalling pathways, two of which are shown. Members of the tumour necrosis factor (TNF) superfamily and the Toll-like receptors and NOD-like receptors (Fig. 4.2) signal through the nuclear factor kappa B (NFκB) pathway. Several other cytokines, including interleukin-2 (IL-2), IL-6 and interferons, employ the Janus kinase/signal transducer and activator of transcription (JAK-STAT) pathway to regulate cellular function (see text for more details). (IkB = inhibitor of kappa B; IKK = I kappa B kinase; P = phosphorylation of the signalling protein; TRAF = tumour necrosis factor receptor-associated factor)

(IFN-γ = interferon gamma; IFN-κB = interferon-kappa B; IgE = immunoglobulin E; NK = natural killer)
transducing signals downstream of many cytokine receptors, including those for IL-2, IL-6 and interferon-gamma (IFN-γ). On receptor binding, JAK proteins are recruited to the intracellular portion of the receptor and are phosphorylated. These in turn phosphorylate STAT proteins, which translocate to the nucleus and activate gene transcription, altering cellular function. The function and disease associations of several important cytokines are shown in Box 4.2. Cytokine inhibitors are now routinely used in the treatment of autoimmune diseases, most of which are monoclonal antibodies to cytokines or their receptors. In addition, small-molecule inhibitors have been developed that inhibit the intracellular signalling pathways used by cytokines. These include the Janus kinase inhibitors tofacitinib and baracitinib, which are used in rheumatoid arthritis (p. 1026), and the tyrosine kinase inhibitor imatinib, which is used in chronic myeloid leukaemia (p. 959).

### Integrins

Integrins are transmembrane proteins that play important roles in cell–cell and cell–matrix interactions. They mediate attachment of the cell to the extracellular matrix, signal transduction and cell migration. Their role in autoimmune disease has been extensively studied. Targeted therapy with a recombinant humanised anti-α4 integrin antibody, natalizumab, is an effective treatment for multiple sclerosis, which works by preventing immune cells from traversing the vascular endothelium and entering the central nervous system (p. 1109).

### Complement

The complement system comprises a group of more than 20 tightly regulated, functionally linked proteins that act to promote inflammation and eliminate pathogens. Complement proteins are produced in the liver and are present in inactive form in the circulation. When the complement system is activated, it sets in motion a rapidly amplified biological cascade analogous to the coagulation cascade (p. 918).

There are three mechanisms by which the complement cascade can be activated (Fig. 4.4):

- **The alternate pathway** is triggered directly by binding of C3 to bacterial cell-wall components, such as lipopolysaccharide of Gram-negative bacteria and teichoic acid of Gram-positive bacteria.
- **The classical pathway** is initiated when two or more IgM or IgG antibody molecules bind to antigen. The associated conformational change exposes binding sites on the antibodies for the first protein in the classical pathway, C1, which is a multiheaded molecule that can bind up to six antibody molecules. Once two or more ‘heads’ of a C1 molecule are bound to antibody, the classical cascade is triggered. An important inhibitor of the classical pathway is C1 inhibitor (C1inh), as illustrated in Figure 4.4.
- **The lectin pathway** is activated by the direct binding of mannose-binding lectin to microbial cell surface carbohydrates. This mimics the binding of C1 to immune complexes and directly stimulates the classical pathway, bypassing the need for immune complex formation.

Activation of complement by any of these pathways results in activation of C3. This in turn activates the final common pathway, in which the complement proteins C5–C9 assemble to form the membrane attack complex (MAC). This can puncture the cell wall, leading to osmotic lysis of target cells. This step is particularly important in the defence against encapsulated bacteria such as Neisseria spp. and Haemophilus influenzae.

Complement fragments generated by activation of the cascade can also act as opsonins, rendering microorganisms more susceptible to phagocytosis by macrophages and neutrophils (see Fig. 4.2). In addition, they are chemotactic agents, promoting leucocyte trafficking to sites of inflammation. Some fragments act as anaphylotoxins, binding to complement receptors on mast cells and triggering release of histamine, which increases vascular permeability. The products of complement activation also help to target immune complexes to antigen-presenting cells, providing a link between the innate and the acquired immune systems. Finally, activated complement products dissolve the immune complexes that triggered the cascade, minimising bystander damage to surrounding tissues.

A monoclonal antibody directed against the central complement molecule C5, eculizumab, has been developed for therapeutic use in paroxysmal nocturnal haemoglobinuria and atypical haemolytic uraemic syndromes (p. 408). Invasive infection, including meningococcal sepsis, has been reported with eculizumab therapy, highlighting the importance of the complement system in preventing such infections.

### Mast cells and basophils

Mast cells and basophils are bone marrow-derived cells that play a central role in allergic disorders. Mast cells reside predominantly in tissues exposed to the external environment, such as the skin and gut, while basophils circulate in peripheral blood and are recruited into tissues in response to inflammation. Both contain large cytoplasmic granules that enclose vasoactive substances such as histamine (see Fig. 4.14). Mast cells and
Natural killer cells

Natural killer (NK) cells are large granular lymphocytes that play a major role in defence against tumours and viruses. They exhibit features of both the adaptive and the innate immune systems in that they are morphologically similar to lymphocytes and recognise similar ligands, but they are not antigen-specific and cannot generate immunological memory. NK cells express a variety of cell surface receptors, some of which are stimulatory and others inhibitory. The effects of inhibitory receptors normally predominate. These recognise human leucocyte antigen (HLA) molecules that are expressed on normal nucleated cells, preventing NK cell-mediated attack, whereas the stimulatory receptors recognise molecules that are expressed primarily when cells are damaged. This allows NK cells to remain tolerant to healthy cells but not to damaged ones. When cells become infected by viruses or undergo malignant change, expression of HLA class I molecules on the cell surface can be down-regulated. This is an important mechanism by which these cells then evade adaptive T-lymphocyte responses. In this circumstance, however, NK cell defences become important, as down-regulation of HLA class I abrogates the inhibitory signals that normally prevent NK activation. The net result is NK attack on the abnormal target cell. NK cells can also be activated by binding of antigen–antibody complexes to surface receptors. This physically links the NK cell to its target in a manner analogous to opsonisation and is known as antibody-dependent cellular cytotoxicity (ADCC).

Activated NK cells can kill their targets in various ways. They secrete pore-forming proteins such as perforin into the membrane of the target cell, and proteolytic enzymes called granzymes into the target cell, which cause apoptosis. In addition, NK cells produce a variety of cytokines such as TNF-α and IFN-γ, which have direct antiviral and anti-tumour effects.

The adaptive immune system

If the innate immune system fails to provide effective protection against an invading pathogen, the adaptive immune system is mobilised (see Fig. 4.1). This has three key characteristics:

- It has exquisite specificity and can discriminate between very small differences in molecular structure.
- It is highly adaptive and can respond to an almost unlimited number of molecules.
- It possesses immunological memory, and changes consequent to initial activation by an antigen allow a more effective immune response on subsequent encounters.

There are two major arms of the adaptive immune response. Humoral immunity involves the production of antibodies by B lymphocytes, and cellular immunity involves the activation of T lymphocytes, which synthesise and release cytokines that affect other cells, as well as directly killing target cells. These interact closely with each other and with the components of the innate immune system to maximise effectiveness of the immune response.

Lymphoid organs

The primary lymphoid organs are involved in lymphocyte development. They include the bone marrow, where T and B lymphocytes differentiate from haematopoietic stem cells (p. 914) and where B lymphocytes also mature, and the thymus, the site of T-cell maturation (see Fig. 4.1). After maturation, lymphocytes migrate to the secondary lymphoid organs. These include the spleen, lymph nodes and mucosa-associated lymphoid tissue. These trap and concentrate foreign substances and are the major sites of interaction between naïve lymphocytes and microorganisms.

The thymus

The thymus is a bi-lobed structure in the anterior mediastinum, and is organised into cortical and medullary areas. The cortex is densely populated with immature T cells, which migrate to the medulla to undergo selection and maturation. The thymus is most active in the fetal and neonatal period, and involutes after puberty. Failure of thymic development is associated with profound T-cell immune deficiency (p. 79) but surgical removal of the thymus in childhood (usually during major cardiac surgery) is not associated with significant immune dysfunction.

The spleen

The spleen is the largest of the secondary lymphoid organs. It is highly effective at filtering blood and is an important site of phagocytosis of senescent erythrocytes, bacteria, immune complexes and other debris, and of antibody synthesis. It is important for defence against encapsulated bacteria, and asplenic individuals are at risk of overwhelming Streptococcus pneumoniae and H. influenzae infection (see Box 4.5).

Lymph nodes

These are positioned to maximise exposure to lymph draining from sites of external contact, and are highly organised (Fig. 4.1)

- The cortex contains primary lymphoid follicles, which are the site of B-lymphocyte interactions. When B cells encounter antigen, they undergo intense proliferation, forming germinal centres.
- The paracortex is rich in T lymphocytes and dendritic cells.
- The medulla is the major site of antibody-secreting plasma cells.
- Within the medulla there are many sinuses, which contain large numbers of macrophages.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT) consists of diffusely distributed lymphoid cells and follicles present along mucosal surfaces. It has a similar function to the more organised, encapsulated lymph nodes. They include the tonsils, adenoids and Peyer’s patches in the small intestine.

Lymphatics

Lymphoid tissue is connected by a network of lymphatics, with three major functions: it provides access to lymph nodes, returns interstitial fluid to the venous system, and transports fat from the small intestine to the blood stream (see Fig. 14.13, p. 372). The lymphatics begin as blind-ending capillaries, which come together to form lymphatic ducts, entering and leaving regional lymph nodes as afferent and efferent ducts, respectively. They eventually coalesce and drain into the thoracic duct and left subclavian vein. Lymphatics may be either deep or superficial, and follow the distribution of major blood vessels.
Humoral immunity

Humoral immunity is mediated by B lymphocytes, which differentiate from haematopoietic stem cells in the bone marrow. Their major functions are to produce antibody and interact with T cells, but they are also involved in antigen presentation. Mature B lymphocytes can be found in the bone marrow, lymphoid tissue, spleen and, to a lesser extent, the blood stream. They express a unique immunoglobulin receptor on their cell surface, the B-cell receptor, which binds to soluble antigen targets (Fig. 4.5). Encounters with antigen usually occur within lymph nodes. If provided with appropriate cytokines and other signals from nearby T lymphocytes, antigen-specific B cells respond by rapidly proliferating in a process known as clonal expansion (Fig. 4.5). This is accompanied by a highly complex series of genetic rearrangements known as somatic hypermutation, which generates B-cell populations that express receptors with greater affinity for antigen than the original. These cells differentiate into either long-lived memory cells, which reside in the lymph nodes, or plasma cells, which produce antibody. Memory cells allow production of a more rapid and more effective response on subsequent exposure to that pathogen.

Immunoglobulins

Immunoglobulins (Ig) play a central role in humoral immunity. They are soluble proteins produced by plasma cells and are made up of two heavy and two light chains (Fig. 4.6). The heavy chain determines the antibody class or isotype, such as IgG, IgA, IgM, IgE or IgD. Subclasses of IgG and IgA also occur. The antigen is recognised by the antigen-binding regions (Fab) of both heavy and light chains, while the consequences of antibody binding are determined by the constant region of the heavy chain (Fc) (Box 4.3). Antibodies have several functions.

Fig. 4.5 B-cell activation. Activation of B cells is initiated through binding of an antigen with the immunoglobulin receptor on the cell surface. For activation to proceed, an interaction with T-helper cells is also required, providing additional signals through binding of CD40 ligand (CD40L) to CD40; an interaction between the T-cell receptor (TCR) and processed antigenic peptides presented by human leucocyte antigen (HLA) molecules on the B-cell surface; and cytokines released by the T-helper cells. Fully activated B cells undergo clonal expansion with differentiation towards plasma cells that produce antibody. Following activation, memory cells are generated that allow rapid antibody responses when the same antigen is encountered on a second occasion. (CD = cluster of differentiation; IL = interleukin)

Fig. 4.6 The structure of an immunoglobulin (antibody) molecule. The variable region is responsible for antigen binding, whereas the constant region can interact with immunoglobulin receptors expressed on immune cells.

*Activation of the classical pathway, also called ‘complement fixation’.
They facilitate phagocytosis by acting as opsonins (see Fig. 4.2) and facilitate cell killing by cytotoxic cells, particularly NK cells by antibody-dependent cellular cytotoxicity. Binding of antibodies to antigen can trigger activation of the classical complement pathway (see Fig. 4.4). In addition, antibodies can directly neutralise the biological activity of their antigen target. This is a particularly important feature of IgA antibodies, which act predominantly at mucosal surfaces.

The humoral immune response is characterised by immunological memory, in which the antibody response to successive exposures to an antigen is qualitatively and quantitatively improved from the first exposure. When a previously unstimulated or ‘naïve’ B lymphocyte is activated by antigen, the first antibody to be produced is IgM, which appears in the serum after 5–10 days. Depending on additional stimuli provided by T lymphocytes, other antibody classes (IgG, IgA and IgE) are produced 1–2 weeks later. If the memory B cell is subsequently re-exposed to the same antigen, the lag time between exposure and production of antibody is decreased to 2–3 days, the amount of antibody produced is increased, and the response is dominated by IgG antibodies of high affinity. Furthermore, in contrast to the initial antibody response, secondary antibody responses do not require additional input from T lymphocytes. This allows the rapid generation of highly specific responses on re-exposure to a pathogen and is an important mechanism in vaccine efficacy.

**Cellular immunity**

Cellular immunity is mediated by T lymphocytes, which play important roles in defence against viruses, fungi and intracellular bacteria. They also play an important immunoregulatory role, by orchestrating and regulating the responses of other components of the immune system. T-lymphocyte precursors differentiate from haematopoietic stem cells in the bone marrow and are exported to the thymus when they are still immature (see Fig. 4.1). Individual T cells express a unique receptor that is highly

![Fig. 4.7 T-cell activation](image-url)
specific for a single antigen. Within the thymus T cells undergo a process of stringent selection to ensure that autoreactive cells are destroyed. Mature T lymphocytes leave the thymus and expand to populate other organs of the immune system. It has been estimated that an individual possesses $10^6–10^7$ T-cell clones, each with a unique T-cell receptor, ensuring at least partial coverage for any antigen encountered.

Unlike B cells, T cells cannot recognise intact protein antigens in their native form. Instead, the protein must be broken down into component peptides by antigen-presenting cells for presentation to T lymphocytes in association with HLA molecules on the antigen-presenting cell surface. This process is known as antigen processing and presentation, and it is the complex of peptide and HLA together that is recognised by individual T cells (Fig. 4.7). The structure of HLA molecules varies widely between individuals. Since each HLA molecule has the capacity to present a subtly different peptide repertoire to T lymphocytes, this ensures enormous diversity in recognition of antigens by the T-cell population. All nucleated cells have the capacity to process and present antigens, but cells with specialised antigen-presenting functions include dendritic cells, macrophages and B lymphocytes. These carry additional co-stimulatory molecules, such as CD80 and CD86, providing the necessary ‘second signal’ for full T-cell activation.

T lymphocytes can be divided into two subgroups on the basis of function and recognition of HLA molecules. These are designated CD4+ and CD8+ T cells, according to the ‘cluster of differentiation’ (CD) antigen number of key proteins expressed on their cell surface.

**CD8+ T lymphocytes**

These cells recognise antigenic peptides in association with HLA class I molecules (HLA-A, HLA-B, HLA-C). They kill infected cells directly through the production of pore-forming molecules such as perforin and release of digesting enzymes triggering apoptosis of the target cell, and are particularly important in defence against viral infection.

**CD4+ T lymphocytes**

These cells recognise peptides presented on HLA class II molecules (HLA-DR, HLA-DP and HLA-DQ) and have mainly immunoregulatory functions. They produce cytokines and provide co-stimulatory signals that support the activation of CD8+ T lymphocytes and assist the production of mature antibody by B cells. In addition, their close interaction with phagocytes determines cytokine production by both cell types. CD4+ lymphocytes can be further subdivided into subsets on the basis of the cytokines they produce:

- **TH1 (T helper) cells** typically produce IL-2, IFN-γ and TNF-α, and support the development of delayed-type hypersensitivity responses (p. 83).
- **TH2 cells** typically produce IL-4, IL-5, IL-10 and IL-13, and promote allergic responses (p. 84).
- **T-regulatory cells (T regs)** are a further subset of specialised CD4+ lymphocytes that are important in actively suppressing activation of other cells and preventing autoimmune disease.
- **TH17 cells** are pro-inflammatory cells defined by their production of IL-17. They are related to regulatory T cells, and play a role in immune defence at mucosal surfaces.

T-cell activation is regulated by a balance between co-stimulatory molecules, the second signal required for activation, and inhibitory molecules that down-regulate T-cell activity. One such inhibitory molecule, CTLA4, has been harnessed therapeutically in the form of abatacept, which is a fusion protein comprised of the Fc fragment of immunoglobulin linked to CTLA4. This is used to inhibit T-cell activation in rheumatoid arthritis and solid organ transplantation.

### The inflammatory response

Inflammation is the response of tissues to injury or infection, and is necessary for normal repair and healing. This section focuses on the general principles of the inflammatory response and its multisystem manifestations. The role of inflammation in specific diseases is discussed in many other chapters of this book.

#### Acute inflammation

Acute inflammation is the result of rapid and complex interplay between the cells and soluble molecules of the innate immune system. The classical external signs include heat, redness, pain and swelling (Fig. 4.8). The inflammatory process is initiated by local tissue injury or infection. Damaged epithelial cells produce cytokines and antimicrobial peptides, causing early infiltration of phagocytic cells. Production of leukotrienes, prostaglandins, histamine, kinins, anaphylatoxins and inducible nitric oxide synthase also occurs within inflamed tissue. These mediators cause vasodilatation and increased vascular permeability, causing trafficking of fluid and cells into the affected tissue. In addition, pro-inflammatory cytokines, such as IL-1, TNF-α and IL-6 produced at the site of injury, are released systemically and act on the hypothalamus to cause fever, and on the liver to stimulate production of acute phase proteins.

#### The acute phase response

The acute phase response refers to the production of a variety of proteins by the liver in response to inflammatory stimuli. These proteins have a wide range of activities. Circulating levels of C-reactive protein (CRP) and serum amyloid A may be increased 1000-fold, contributing to host defence and stimulating repair and regeneration. Fibrinogen plays an essential role in wound healing, and α1-antitrypsin and α1-antichymotrypsin control the pro-inflammatory cascade by neutralising the enzymes produced by activated neutrophils, preventing widespread tissue destruction. In addition, antioxidants such as haptoglobin and manganese superoxide dismutase scavange for oxygen free radicals, while increased levels of iron-binding proteins such as ferritin and lactoferrin decrease the iron available for uptake by bacteria (p. 941). Immunoglobulins are not acute phase proteins but are often increased in chronic inflammation.

#### Septic shock

Septic shock is the clinical manifestation of overwhelming inflammation (p. 196). It is characterised by excessive production of pro-inflammatory cytokines by macrophages, causing hypotension, hypovaemia and tissue oedema. In addition, uncontrolled neutrophil activation causes release of proteases and oxygen free radicals within blood vessels, damaging the vascular endothelium and further increasing capillary permeability. Direct activation of the coagulation pathway combines with endothelial cell disruption to form clots within the damaged vessels. The
The inflammatory response

Chronic inflammation

In most instances, the development of an active immune response results in clearance and control of the inflammatory stimulus and resolution of tissue damage. Failure of this process may result in chronic inflammation, with significant associated bystander damage, known as hypersensitivity responses. Persistence of microorganisms can result in ongoing accumulation of neutrophils, macrophages and activated T lymphocytes within the lesion. If this is associated with local deposition of fibrous tissue, a granuloma may form. Granulomas are characteristic of tuberculosis and leprosy (Hansen’s disease), in which the microorganism is protected by a robust cell wall that shields it from killing, despite phagocytosis.

Resolution of inflammation

Resolution of an inflammatory response is crucial for normal healing. This involves active down-modulation of inflammatory stimuli and repair of bystander damage to local tissues. Extravasated neutrophils undergo apoptosis and are phagocytosed by macrophages, along with the remains of microorganisms. Macrophages also synthesise collagenase and elastase, which break down local connective tissue and aid in the removal of debris. Normal tissue homeostasis is also associated with reversion of parenchymal cells to a non-inflammatory phenotype. Macrophage-derived cytokines, including transforming growth factor-beta (TGF-β) and platelet-derived growth factor, stimulate fibroblasts and promote the synthesis of new collagen, while angiogenic factors stimulate new vessel formation.

Laboratory features of inflammation

Inflammation is associated with changes in many laboratory investigations. Leucocytosis is common, and reflects the transit of activated neutrophils and monocytes to the site of infection. The platelet count may also be increased. The most widely used laboratory measure of acute inflammation is CRP. Circulating
levels of many other acute phase reactants, including fibrinogen, ferritin and complement components, are also increased in response to acute inflammation, while albumin levels are reduced. Chronic inflammation is frequently associated with a normochromatic normochromic anaemia (p. 943).

### C-reactive protein

C-reactive protein (CRP) is an acute phase reactant synthesised by the liver, which opsonises invading pathogens. Circulating concentrations of CRP increase within 6 hours of the start of an inflammatory stimulus. Serum concentrations of CRP provide a direct biomarker of acute inflammation and, because the serum half-life of CRP is 18 hours, levels fall promptly once the inflammatory stimulus is removed. Sequential measurements are useful in monitoring disease activity (Box 4.4). For reasons that remain unclear, some diseases are associated with only minor elevations of CRP despite unequivocal evidence of active inflammation. These include systemic lupus erythematosus (SLE), systemic sclerosis, ulcerative colitis and leukaemia. An important practical point is that if the CRP is raised in these conditions, it suggests intercurrent infection rather than disease activity. Since the CRP is a more sensitive early indicator of the acute phase response, it is generally used in preference to the erythrocyte sedimentation rate (ESR). If both ESR and CRP are used, any discrepancy should be resolved by assessing the individual determinants of the ESR, which are discussed below.

### Erythrocyte sedimentation rate

The ESR is an indirect measure of inflammation. It measures how fast erythrocytes fall through plasma, which is determined by the composition of plasma proteins and the morphology of circulating erythrocytes. These factors govern the propensity of red cells to aggregate, the major determinant of the ESR. Erythrocytes are inherently negatively charged, which prevents them from clumping together in the blood stream. Since plasma proteins are positively charged, an increase in plasma protein concentrations neutralises the negative charge of erythrocytes, overcoming their inherent repulsive forces and causing them aggregate, resulting in rouleaux formation. Rouleaux have a higher mass-to-surface area ratio than single red cells, and therefore sediment faster. The most common reason for an increased ESR is an acute phase response, which causes an increase in the concentration of acute phase proteins, including CRP. However, other conditions that do not affect acute phase proteins may alter the composition and concentration of other plasma protein (Box 4.4). For example, immunoglobulins comprise a significant proportion of plasma proteins but do not participate in the acute phase response. Thus any condition that causes an increase in serum immunoglobulins will increase the ESR without a corresponding increase in CRP. In addition, abnormal red cell morphology can make rouleaux formation impossible. For these reasons, an inappropriately low ESR occurs in spherocytosis and sickle-cell anaemia.

#### Plasma viscosity

Plasma viscosity is another surrogate measure of plasma protein concentration. Like the ESR, it is affected by the concentration of large plasma proteins, including fibrinogen and immunoglobulins. It is not affected by properties of erythrocytes and is generally considered to be more reliable than the ESR as a marker of inflammation.

Presenting problems in immune disorders

Recurrent infections

Infections can occur in otherwise healthy individuals but recurrent infection raises suspicion of an immune deficiency. Depending on the component of the immune system affected, the infections may involve bacteria, viruses, fungi or protozoa, as summarised in Box 4.5. T-cell deficiencies can involve pathogens from all groups.

Aetiology

Infections secondary to immune deficiency occur because of defects in the number or function of phagocytes, B cells, T cells or complement, as described later in this chapter.

Clinical assessment

Clinical features that may indicate immune deficiency are listed in Box 4.6. Frequent or severe infections, or ones caused by unusual organisms or at unusual sites are typical of immune deficiency.

Investigations

Initial investigations should include full blood count and white cell differential, CRP, renal and liver function tests, urine dipstick, serum immunoglobulins with protein electrophoresis, and HIV testing. Additional microbiological tests, virology and imaging are required to identify the causal organism and localise the site of infection, as outlined in Box 4.7. If primary immune deficiency is suspected on the basis of initial investigations, more specialised tests should be considered, as summarised in Box 4.8.

Management

If an immune deficiency is suspected but has not yet been formally characterised, patients should not receive live vaccines because of the risk of vaccine-induced disease. Further management depends on the underlying cause and details are provided later.

(NK = natural killer)

### Intermittent fever

Intermittent fever has a wide differential diagnosis, including recurrent infection, malignancy and certain rheumatic disorders, such as Still’s disease, vasculitis and SLE (pp. 1040 and 1034), but a familial fever syndrome is a potential cause.

**Aetiology**

Familial fever syndromes are genetic disorders caused by mutations in genes responsible for regulating the inflammatory response. The symptoms are caused by activation of intracellular signalling pathways involved in the regulation of inflammation, with over-production of pro-inflammatory cytokines such as IL-1.

**Clinical assessment**

A full clinical history and physical examination should be performed, paying attention to the patient’s ethnic background and any family history of a similar disorder. If this assessment shows no evidence of underlying infection, malignancy or a rheumatic disorder and there is a positive family history and early age at onset, then the likelihood of a familial fever syndrome is increased.

**Investigations**

Blood should be taken for a full blood count, measurement of ESR and CRP, and assessment of renal and liver function. Serum ferritin should be checked, as very high levels support the diagnosis of Still’s disease. Blood and urine cultures should also be performed, along with an autoimmune screen that includes measurement of antinuclear antibodies and consideration of antineutrophil cytoplasmic antibodies to check for evidence of SLE or vasculitis, respectively. Imaging may be required to exclude occult infection. If these investigations provide no evidence of infection or another cause, then genetic analysis should be considered to confirm the diagnosis of a familial fever syndrome (p. 81). Negative genetic testing does not, however, entirely exclude a periodic fever syndrome.

**Management**

Symptomatic management with non-steroidal anti-inflammatory drugs (NSAIDs) should be initiated, pending the results of investigations. If the response to NSAIDs is inadequate, glucocorticoids can be tried, provided that infection has been excluded. If a familial fever syndrome is confirmed, then definitive therapy should be initiated, depending on the underlying diagnosis (p. 81).
Anaphylaxis is a potentially life-threatening, systemic allergic reaction characterised by circulatory collapse, bronchoconstriction, laryngeal stridor, often associated with angioedema, and urticaria. The risk of death is increased in patients with pre-existing asthma, particularly if this is poorly controlled, and in situations where treatment with adrenaline (epinephrine) is delayed.

### Aetiology

Anaphylaxis occurs when an allergen binds to and cross-links membrane-bound IgE on mast cells in a susceptible individual, causing release of histamine, tryptase and other vasoactive mediators from mast cells. These mediators have a variety of effects, including vasodilatation, increased capillary permeability leading to hypotension, and bronchoconstriction, as summarised in Box 4.9. It can be difficult to distinguish IgE-mediated anaphylaxis clinically from non-specific degranulation of mast cells on exposure to drugs, chemicals or other triggers where IgE is not involved, previously known as anaphylactoid reactions. Common triggers are shown in Box 4.10.

### Clinical assessment

The clinical features of anaphylaxis and ‘anaphylactoid’ reactions are indistinguishable and are summarised in Figure 4.9. Several other conditions can mimic anaphylaxis and these are listed in Box 4.11.

It is important to assess the severity of the reaction, and the time between allergen exposure and onset of symptoms provides

  - Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs)
  - Opiates
  - Radiocontrast media

- **Physical**
  - Exercise
  - Cold

- **Idiopathic**
  - No cause is identified in 20% of patients with anaphylaxis

---

**Fig. 4.9 Clinical manifestations of anaphylaxis.** In this example, the response is to an insect sting containing venom to which the patient is allergic. This causes release of histamine and other vasoactive mediators, which cause the characteristic features of anaphylaxis that are illustrated.
a guide. Enquiry should be made about potential triggers. If none is immediately obvious, a detailed history of the previous 24 hours may be helpful. The most common triggers of anaphylaxis are foods, latex, insect venom and drugs (see Box 4.10). A history of previous local allergic responses to the offending agent is common. The route of allergen exposure may influence the principal clinical features of a reaction; for example, if an allergen is inhaled, the major symptom is frequently wheezing. Features of anaphylaxis may overlap with the direct toxic effects of drugs and venom (Chs 7 and 8). Potentiating factors, such as exercise or alcohol, can lower the threshold for an anaphylactic event. It is important to identify precipitating factors so that appropriate avoidance measures may be taken in the longer term.

**Investigations**

Measurement of serum mast cell tryptase concentrations is useful to confirm the diagnosis but cannot distinguish between anaphylaxis and non-IgE-mediated anaphylactoid reactions. Specific IgE tests may be useful in confirming hypersensitivity and may be preferable to skin-prick tests when investigating patients with a history of anaphylaxis.
Immune deficiency

The consequences of immune deficiency include recurrent infection, autoimmunity as a result of immune dysregulation, and increased susceptibility to malignancy, especially malignancy driven by viral infections such as Epstein–Barr virus. Immune deficiency may arise through intrinsic defects in immune function but is much more commonly due to secondary causes, including infection, drug therapy, malignancy and ageing. This section gives an overview of primary immune deficiencies. More than a hundred such deficiencies have been described, most of which are genetically determined and present in childhood or adolescence. The presentation of immune deficiency depends on the component of the immune system that is defective (see Box 4.5). There is considerable overlap and redundancy in the immune network, however, and some diseases do not fall easily into this classification.

Primary phagocyte deficiencies

Primary phagocyte deficiencies typically present with recurrent bacterial and fungal infections, which may involve unusual sites. Affected patients require aggressive management of infections, including intravenous antibiotics and surgical drainage of abscesses, and long-term prophylaxis with antibacterial and antifungal agents. The most important examples are illustrated in Figure 4.10 and discussed below.

Chronic granulomatous disease

This is caused by mutations in genes that encode NADPH oxidase enzymes, which results in failure of oxidative killing. The defect leads to susceptibility to catalase-positive organisms such as Staphylococcus aureus, Burkholderia cenocepacia and Aspergillus. Intracellular killing of mycobacteria in macrophages is also impaired. Infections most commonly involve the lungs, lymph nodes, soft tissues, bone, skin and urinary tract, and are characterised histologically by granuloma formation. Most cases are X-linked (p. 48).

Leucocyte adhesion deficiencies

These very rare disorders of phagocyte migration occur because of failure to express adhesion molecules on the surface of leucocytes, resulting in their inability to exit the blood stream. The most common cause is loss-of-function mutations affecting the ITGB2 gene, which encodes the integrin β-2 chain, a component of the adhesion molecule LFA1. They are characterised by recurrent bacterial infections but sites of infection lack evidence of neutrophil infiltration, such as pus formation. Peripheral blood neutrophil counts may be very high during acute infection because of the failure of mobilised neutrophils to exit blood vessels. Specialised tests show reduced or absent expression of adhesion molecules on neutrophils.

Fig. 4.10 Normal phagocyte function and mechanisms of primary phagocyte deficiency. Under normal circumstances, neutrophils traverse the endothelium to enter tissues by the cell surface molecule lymphocyte function-associated antigen 1 (LFA1), which binds to intercellular adhesion molecule 1 (ICAM1) on endothelium. In order for macrophages to engulf and kill microorganisms, they need to be activated by cytokines and also require nicotinamide adenine dinucleotide phosphate (NADPH) oxidase to generate free radicals. Primary phagocyte deficiencies can occur as the result of leucocytes being unable to traverse endothelium due to defects in LFA1, because of mutations in cytokines or their receptors, or because of defects in NADPH oxidase. (IFN-γ = interferon-gamma; IL = interleukin)
Defects in cytokines and cytokine receptors
Mutations of the genes encoding cytokines such as IFN-γ, IL-12, IL-23 or their receptors result in failure of intracellular killing by macrophages, and affected individuals are particularly susceptible to mycobacterial infections.

**Complement pathway deficiencies**

Loss-of-function mutations have been identified in almost all the complement pathway proteins (see Fig. 4.4). While most complement deficiencies are rare, mannose-binding lectin deficiency is common and affects about 5% of the northern European population, many of whom are asymptomatic (see below).

**Clinical features**

Patients with deficiency in complement proteins can present in different ways. In some cases, the presenting feature is recurrent infection with encapsulated bacteria, particularly *Neisseria* spp., reflecting the importance of the membrane attack complex in defence against these organisms. However, genetic deficiencies of the classical complement pathway (C1, C2 and C4) also present with an increased risk of autoimmune disease, particularly SLE (p. 1034). Individuals with mannose-binding lectin deficiency have an increased incidence of bacterial infections if subjected to an additional cause of immune compromise, such as premature birth or chemotherapy. The significance of this condition has been debated, however, since population studies have shown no overall increase in infectious disease or mortality in patients with this disorder. Deficiency of the regulatory protein C1 inhibitor is not associated with recurrent infection but causes recurrent angioedema (p. 87).

**Investigations**

Screening for complement deficiencies usually involves specialised functional tests of complement-mediated haemolysis. These are known as the CH50 (classical haemolytic pathway 50) and AP50 (alternative pathway 50) tests. If abnormal, haemolytic tests are followed by measurement of individual complement components.

**Management**

Patients with complement deficiencies should be vaccinated with meningococcal, pneumococcal and *H. influenzae* B vaccines to boost their adaptive immune responses. Lifelong prophylactic penicillin to prevent meningococcal infection is recommended, as is early access to acute medical assessment in the event of infection. Patients should also carry a MedicAlert or similar. At-risk family members should be screened for complement deficiencies with functional complement assays. The management of C1 esterase deficiency is discussed elsewhere.

**Primary antibody deficiencies**

Primary antibody deficiencies occur as the result of abnormalities in B-cell function, as summarised in Figure 4.11. They are characterised by recurrent bacterial infections, particularly of the respiratory and gastrointestinal tract. The most common causative organisms are encapsulated bacteria such as *Streptococcus pneumoniae* and *H. influenzae*. These disorders usually present in infancy, when the protective benefit of placental transfer of maternal immunoglobulin has waned. The most important causes are discussed in more detail below.

**X-linked agammaglobulinaemia**

This rare X-linked disorder (p. 48) is caused by mutations in the *BTK* gene, which encodes Bruton tyrosine kinase, a signalling protein that is required for B-cell development. Affected males present with severe bacterial infections during infancy. There is a marked reduction in B-cell numbers and immunoglobulin levels are low or undetectable (<0.05 g/L). In some

**Selective IgA deficiency**

This is the most common primary antibody deficiency, affecting 1:600 northern Europeans. Although IgA deficiency is usually asymptomatic with no clinical sequelae, about 30% of individuals experience recurrent mild respiratory and gastrointestinal infections. The diagnosis can be confirmed by measurement of IgA levels, which are low or undetectable (<0.05 g/L). In some
Specific treatment is generally not required. Patients, there is a compensatory increase in serum IgG levels. Specific treatment is generally not required.

Common variable immune deficiency
Common variable immune deficiency (CVID) is characterised by low serum IgG levels and failure to make antibody responses to exogenous pathogens. It is a heterogeneous adult-onset primary immune deficiency of unknown cause. The presentation is with recurrent infections, and bronchiectasis is a recognised complication. Paradoxically, antibody-mediated autoimmune diseases, such as idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia, are common in CVID. It is also associated with an increased risk of malignancy, particularly lymphoproliferative disease.

Functional IgG antibody deficiency
This is a poorly characterised condition resulting in defective antibody responses to polysaccharide antigens. Some patients are also deficient in the antibody subclasses IgG2 and IgG4, and this condition was previously called IgG subclass deficiency. There is an overlap between specific antibody deficiency, IgA deficiency and CVID, and some patients may progress to a more global antibody deficiency over time.

Investigations
Serum immunoglobulins (Box 4.15) should be measured in conjunction with protein and urine electrophoresis to exclude secondary causes of hypogammaglobulinaemia, and B- and T-lymphocyte subsets should be measured. Specific antibody responses to known pathogens should be assessed by measuring IgG antibodies against tetanus, H. influenzae and S. pneumoniae (most patients will have been exposed to these antigens through infection or immunisation). If specific antibody levels are low, immunisation with the appropriate killed vaccine should be followed by repeat antibody measurement 6–8 weeks later; failure to mount a response indicates a significant defect in antibody production. These functional tests have generally superseded IgG subclass quantitation.

Management
Patients with antibody deficiencies generally require aggressive treatment of infections and prophylactic antibiotics may be indicated. An exception is deficiency of IgA, which usually does not require treatment. The mainstay of treatment in most patients with antibody deficiency is immunoglobulin replacement therapy. This is derived from plasma from hundreds of donors and contains IgG antibodies to a wide variety of common organisms. Replacement immunoglobulin may be administered either intravenously or subcutaneously, with the aim of maintaining trough IgG levels (the IgG level just prior to an infusion) within the normal range. This has been shown to minimise progression of end-organ damage and improve clinical outcome. Treatment may be self-administered and is life-long. Benefits of immunisation are limited because of the defect in IgG antibody production, and as with all primary immune deficiencies, live vaccines should be avoided.

Primary T-lymphocyte deficiencies
These are a group of diseases characterised by recurrent viral, protozoal and fungal infections (see Box 4.5). Many T-cell deficiencies are also associated with defective antibody production because of the importance of T cells in providing help for B cells. These disorders generally present in childhood. Several causes of T-cell deficiency are recognised. These are summarised in Figure 4.12 and discussed in more detail below.

DiGeorge syndrome
This results from failure of development of the third and fourth pharyngeal pouches, and is usually caused by a deletion of chromosome 22q11. The immune deficiency is accounted for by failure of thymic development; however, the immune deficiency can be very heterogeneous. Affected patients tend to have very low numbers of circulating T cells despite normal development in the bone marrow. It is associated with multiple developmental anomalies, including congenital heart disease, hypoparathyroidism, tracheo-oesophageal fistulae, cleft lip and palate.

Bare lymphocyte syndromes
These rare disorders are caused by mutations in a variety of genes that regulate expression of HLA molecules or their transport to the cell surface. If HLA class I molecules are affected, CD8+ lymphocytes fail to develop normally, while absent expression of HLA class II molecules affects CD4+ lymphocyte maturation. In addition to recurrent infections, failure to express HLA class I is associated with systemic vasculitis caused by uncontrolled activation of NK cells.

Severe combined immune deficiency
Severe combined immune deficiency (SCID) results from mutations in a number of genes that regulate lymphocyte development, with failure of T-cell maturation, with or without accompanying B- and NK-cell maturation. The most common cause is X-linked SCID, resulting from loss-of-function mutations in the interleukin-2 receptor gamma (IL2RG) gene. The gene product is a component of several interleukin receptors, including those for IL-2, IL-7 and IL-15, which are absolutely required for T-cell and NK development. This results in T-cell-negative, NK-cell-negative,
B-cell-positive SCID. Another cause is deficiency of the enzyme adenosine deaminase (ADA), which causes lymphocyte death due to accumulation of toxic purine metabolites intracellularly, resulting in T-cell-negative, B-cell-negative and NK-cell-negative SCID.

The absence of an effective adaptive immune response causes recurrent bacterial, fungal and viral infections soon after birth. Bone marrow transplantation (BMT; p. 936) is the treatment option of first choice. Gene therapy has been approved for treatment of ADA deficiency when there is no suitable donor for BMT and is under investigation for a number of other causes of SCID.

**Investigations**

The principal tests for T-lymphocyte deficiencies are a total lymphocyte count and quantitation of individual lymphocyte subpopulations. Serum immunoglobulins should also be measured. Second-line, functional tests of T-cell activation and proliferation may be indicated. Patients in whom T-lymphocyte deficiencies are suspected should be tested for HIV infection (p. 310).

**Management**

Patients with T-cell deficiencies should be considered for anti-Pneumocystis and antifungal prophylaxis, and require aggressive management of infections when they occur. Immunglobulin replacement is indicated for associated defective antibody production. Stem cell transplantation (p. 936) or gene therapy may be appropriate in some disorders. Where a family history is known and antenatal testing confirms a specific defect, stem cell therapy prior to recurrent invasive infection can improve outcome.

### Autoimmune lymphoproliferative syndrome

This rare disorder is caused by failure of normal lymphocyte apoptosis, most commonly due to mutations in the FAS gene, which encodes Fas, a signalling protein that regulates programmed cell death in lymphocytes. This results in massive accumulation of autoreactive T cells, which cause autoimmune-mediated anaemia, thrombocytopenia and neutropenia. Other features include lymphadenopathy, splenomegaly and a variety of other autoimmune diseases. Susceptibility to infection is increased because of the neutropenia.

### Secondary immune deficiencies

Secondary immune deficiencies are much more common than primary immune deficiencies and occur when the immune system is compromised by external factors (Box 4.16). Common causes include infections, such as HIV and measles, and cytotoxic...
Periodic fever syndromes

These rare disorders are characterised by recurrent episodes of fever and inflammation, associated with an elevated acute phase response (p. 74).

Familial Mediterranean fever

Familial Mediterranean fever (FMF) is the most common of the familial periodic fevers, predominantly affecting Mediterranean people, including Arabs, Turks, Sephardic Jews and Armenians. It results from mutations of the MEFV gene, which encodes a protein called pyrin that regulates neutrophil-mediated inflammation by indirectly suppressing the production of IL-1. FMF is characterised by recurrent painful attacks of fever associated with peritonitis, pleuritis and arthritis, which last for a few hours to 4 days and are associated with markedly increased CRP levels. Symptoms resolve completely between episodes. Most individuals have their first attack before the age of 20. The major complication of FMF is AA amyloidosis (see below). Colchicine significantly reduces the number of febrile episodes in 90% of patients but is ineffective during acute attacks.

Mevalonic aciduria (mevalonate kinase deficiency)

Mevalonate kinase deficiency, previously known as hyper-IgD syndrome, is an autosomal recessive disorder that causes recurrent attacks of fever, abdominal pain, diarrhea, lymphadenopathy, arthralgia, skin lesions and aphthous ulceration. Most patients are from Western Europe, particularly the Netherlands and northern France. It is caused by loss-of-function mutations in the gene encoding mevalonate kinase, which is involved in the metabolism of cholesterol. It remains unclear why this causes an inflammatory periodic fever. Serum IgD and IgA levels may be persistently elevated, and CRP levels are increased during acute attacks. Standard anti-inflammatory drugs, including colchicine and glucocorticoids, are ineffective in suppressing the attacks but IL-1 inhibitors, such as anakinra, and TNF inhibitors, such as etanercept, may improve symptoms and can induce complete remission in some patients.

TNF receptor-associated periodic syndrome

TNF receptor-associated periodic syndrome (TRAPS) also known as Hibernian fever, is an autosomal dominant syndrome caused by mutations in the TNFRSF1A gene. The presentation is with recurrent attacks of fever, arthralgia, myalgia, serositis and rashes. Attacks may be prolonged for 1 week or more. During a typical attack, laboratory findings include neutrophilia, increased CRP and elevated IgA levels. The diagnosis can be confirmed by low serum levels of the soluble type 1 TNF receptor and by mutation screening of the TNFRSF1A gene. As in FMF, the major complication is amyloidosis, and regular screening for proteinuria is advised. Acute episodes respond to systemic glucocorticoids. Therapy with IL-1 inhibitors, such as anakinra, can be effective in preventing attacks.

Amyloidosis

Amyloidosis is the name given to a group of acquired and hereditary disorders characterised by the extracellular deposition of insoluble proteins.

Pathophysiology

Amyloidosis is caused by deposits consisting of fibrils of the specific protein involved, linked to glycosaminoglycans, proteoglycans and serum amyloid P. Protein accumulation may be localised or systemic, and the clinical manifestations depend on the organ(s) affected. Amyloid diseases are classified by the aetiology and type of protein deposited (Box 4.18).

Clinical features

The clinical presentation may be with nephrotic syndrome (p. 395), cardiomyopathy (p. 538) or peripheral neuropathy (p. 1138). Amyloidosis should always be considered as a potential diagnosis in patients with these disorders when the cause is unclear.

Investigations

The diagnosis is established by biopsy, which may be of an affected organ, rectum or subcutaneous fat. The pathognomonic histological feature is apple-green birefringence of amyloid deposits when stained with Congo red dye and viewed under polarised light. Immunohistochemical staining can identify the type of amyloid fibril present. Quantitative scintigraphy with radiolabelled serum amyloid P is a valuable tool in determining the overall load and distribution of amyloid deposits.

Management

The aims of treatment are to support the function of affected organs and, in acquired amyloidosis, to prevent further amyloid deposition through treatment of the primary cause. When the latter is possible, regression of existing amyloid deposits may occur.

Autoimmune disease

Autoimmunity can be defined as the presence of immune responses against self-tissue. This may be a harmless phenomenon, identified
Those determining cytokine activity, co-stimulation (the expression of second signals required for full T-cell activation; see Fig. 4.7) and cell death. Many of the same gene variants underlie multiple autoimmune disorders, reflecting their common pathogenesis (Box 4.19). Even though some of these associations are the strongest that have been identified in complex genetic diseases, only by the presence of low-titre autoantibodies or autoreactive T cells. However, if these responses cause significant organ damage, autoimmune diseases occur. These are a major cause of chronic morbidity and disability, affecting up to 1 in 30 adults at some point during life.

Pathophysiology

Autoimmune diseases result from the failure of immune tolerance, the process by which the immune system recognises and accepts self-tissue. Central immune tolerance occurs during lymphocyte development, when T and B lymphocytes that recognise self-antigens are eliminated before they develop into fully immunocompetent cells. This process is most active in fetal life but continues throughout life as immature lymphocytes are generated. Some autoreactive cells inevitably evade deletion and escape into the circulation, however, and are controlled through peripheral tolerance mechanisms. Peripheral immune tolerance mechanisms include the suppression of autoreactive cells by regulatory T cells; the generation of functional hyporesponsiveness (anergy) in lymphocytes that encounter antigen in the absence of the co-stimulatory signals that accompany inflammation; and cell death by apoptosis. Autoimmune diseases develop when self-reactive lymphocytes escape from these tolerance mechanisms.

Multiple genetic and environmental factors contribute to the development of autoimmune disease. Autoimmune diseases are much more common in women than in men, for reasons that remain unclear. Many are associated with genetic variations in the HLA loci, reflecting the importance of HLA genes in shaping lymphocyte responses. Other important susceptibility genes include
they have very limited predictive value and are generally not useful in determining management of individual patients. Several environmental factors may be associated with autoimmunity in genetically predisposed individuals, including infection, cigarette smoking and hormone levels. The most widely studied of these is infection, as occurs in acute rheumatic fever following streptococcal infection or reactive arthritis following bacterial infection. Several mechanisms have been invoked to explain the autoimmunity that occurs after an infectious trigger. These include cross-reactivity between proteins expressed by the pathogen and the host (molecular mimicry), such as Guillain–Barré syndrome and Campylobacter infection (p. 1140); release of sequestered antigens from tissues that are damaged during infections that are not usually visible to the immune system; and production of inflammatory cytokines that overwhelm the normal control mechanisms that prevent bystander damage. Occasionally, autoimmune disease may be an adverse effect of drug treatment. For example, metabolic products of the anaesthetic agent halothane can bind to liver enzymes, resulting in a structurally novel protein that is recognised as a foreign antigen by the immune system. This can provoke the development of autoantibodies and activated T cells, which can cause hepatic necrosis.

Clinical features

The clinical presentation of autoimmune disease is highly variable. Autoimmune diseases can be classified by organ involvement or by the predominant mechanism responsible for tissue damage. The Gell and Coombs classification of hypersensitivity is the most widely used, and distinguishes four types of immune response that result in tissue damage (Box 4.20).

- **Type I hypersensitivity** is relevant in allergy but is not associated with autoimmune disease.
- **Type II hypersensitivity** causes injury to a single tissue or organ and is mediated by specific autoantibodies.
- **Type III hypersensitivity** results from deposition of immune complexes, which initiate activation of the classical complement cascade, as well as recruitment and activation of phagocytes and CD4+ lymphocytes. The site of immune complex deposition is determined by the relative amount of antibody, size of the immune complexes, nature of the antigen and local haemodynamics. Generalised deposition of immune complexes gives rise to systemic diseases such as SLE.
- **Type IV hypersensitivity** is mediated by activated T cells and macrophages, which together cause tissue damage.

### Investigations

**Autoantibodies**

Many autoantibodies have been identified and are used in the diagnosis and monitoring of autoimmune diseases, as discussed elsewhere in this book. Antibodies can be quantified either by titre (the maximum dilution of the serum at which the antibody can be detected) or by concentration in standardised units using an enzyme-linked immunosorbent assay (ELISA) in which the antigen is used to coat microtitre plates to which the patient’s serum is added (Fig. 4.13A). Qualitative tests are also employed for antinuclear antibodies in which the pattern of nuclear staining is recorded (Fig. 4.13B).

**Fig. 4.13** Autoantibody testing. **A** Measurement of antibody levels by enzyme-linked immunosorbent assay (ELISA). The antigen of interest is used to coat microtitre plates to which patient serum is added. If autoantibodies are present, these bind to the target antigen on the microtitre plate. The amount of bound antibody is quantitated by adding a secondary antibody linked to an enzyme that converts a colourless substrate to a coloured one, which can be detected by a plate reader. **B** Qualitative analysis of autoantibodies by patterns of nuclear staining. In this assay, patient serum is added to cultured cells and a secondary antibody is added with a fluorescent label to detect any bound antibody. If antinuclear antibodies are present, they are detected as bright green staining. Different antinuclear antibody patterns may be seen in different types of connective tissue disease (Ch. 24). ### 4.20 Gell and Coombs classification of hypersensitivity diseases
Complement

Measurement of complement components can be useful in the evaluation of immune complex-mediated diseases. Classical complement pathway activation leads to a decrease in circulating C4 levels and is often also associated with decreased C3 levels. Serial measurement of C3 and C4 is a useful surrogate measure of disease activity in conditions such as SLE.

Cryoglobulins

Cryoglobulins are antibodies directed against other immunoglobulins, forming immune complexes that precipitate in the cold. They can lead to type III hypersensitivity reactions, with typical clinical manifestations including purpuric rash, often of the lower extremities, arthralgia and peripheral neuropathy. Cryoglobulins are classified into three types, depending on the properties of the immunoglobulin involved (Box 4.21). Testing for cryoglobulins requires the transport of a serum specimen to the laboratory at 37°C. Cryoglobulins should not be confused with cold agglutinins; the latter are autoantibodies specifically directed against the I/i antigen on the surface of red cells, which can cause intravascular haemolysis in the cold (p. 950).

Pathophysiology

The immune system does not normally respond to the many environmental substances to which it is exposed on a daily basis. In allergic individuals, however, an initial exposure to a normally harmless exogenous substance (known as an allergen) triggers the production of specific IgE antibodies by activated B cells. These bind to high-affinity IgE receptors on the surface of mast cells, a step that is not itself associated with clinical sequelae. However, re-exposure to the allergen binds to and cross-links membrane-bound IgE, which activates the mast cells, releasing a variety of vasoactive mediators (the early phase response; Fig. 4.14 and see Box 4.9). This type I hypersensitivity reaction forms the basis of an allergic reaction, which can range from sneezing and rhinorrhea to anaphylaxis (Box 4.22). In some individuals, the early phase response is followed by persistent activation of mast cells, manifest by ongoing swelling and local inflammation. This is known as the late phase reaction and is mediated by mast cell metabolites, basophils, eosinophils and macrophages. Long-standing or recurrent allergic inflammation may give rise to a chronic inflammatory response characterised by a complex infiltrate of macrophages, eosinophils and T lymphocytes, in addition to mast cells and basophils. Once this has been established, inhibition of mast cell mediators with antihistamines is clinically ineffective in isolation. Mast cell activation may also be non-specifically triggered through other signals, such as neuropeptides, anaphylotoxins and bacterial peptides.

The increasing incidence of allergic diseases is largely unexplained but one widely held theory is the ‘hygiene hypothesis’. This proposes that infections in early life are critically important in maturation of the immune response and bias the immune system against the development of allergies; the high prevalence

Allergy

Allergic diseases are a common and increasing cause of illness, affecting between 15% and 20% of the population at some time.
Allergy

Insect venom allergy

Local non-IgE-mediated reactions to insect stings are common and may cause extensive swelling around the site lasting up to 7 days. These usually do not require specific treatment. Toxic reactions to venom after multiple (50–100) simultaneous stings may mimic anaphylaxis. In addition, exposure to large amounts of insect venom frequently stimulates the production of IgE antibodies, and thus may be followed by allergic reactions to single stings. Allergic IgE-mediated reactions vary from mild to life-threatening. Antigen-specific immunotherapy (desensitisation; see below) with bee or wasp venom can reduce the incidence of recurrent anaphylaxis from 50–60% to approximately 10% but requires up to 5 years of treatment.

Peanut allergy

Peanut allergy is the most common food-related allergy. More than 50% of patients present before the age of 3 years and some individuals react to their first known exposure to peanuts, thought to result from sensitisation to arachis oil in topical creams. Peanuts are ubiquitous in the Western diet, and every year up to 25% of peanut-allergic individuals experience a reaction as a result of inadvertent exposure.

Birch oral allergy syndrome

This syndrome is characterised by the combination of birch pollen hay fever and local oral symptoms, including itch and angioedema, after contact with certain raw fruits, raw vegetables and nuts. Cooked fruits and vegetables are tolerated without difficulty. It is due to shared or cross-reactive allergens that are destroyed by cooking or digestion, and can be confirmed by skin prick testing using fresh fruit. Severe allergic reactions are unusual.

Diagnosis

When assessing a patient with a complaint of allergy, it is important to identify what the patient means by the term, as up to 20% of the UK population describe themselves as having a food allergy; in fact, less than 1% have true allergy, as defined by an IgE-mediated hypersensitivity reaction confirmed on double-blind challenge. The nature of the symptoms should be established and specific triggers identified, along with the predictability of a reaction, and the time lag between exposure to a potential allergen and onset of symptoms. An allergic reaction usually occurs within minutes of exposure and provokes predictable, reproducible symptoms such as angioedema, urticaria and wheezing. Specific enquiry should be made about other allergic symptoms, past and present, and about a family history of allergic disease. Potential allergens in the home and workplace should be identified. A detailed drug history should always be taken, including details of adherence to medication, possible adverse effects and the use of over-the-counter or complementary therapies.
Investigations

Skin-prick tests
Skin-prick testing is a key investigation in the assessment of patients suspected of having allergy. A droplet of diluted standardised allergen is placed on the forearm and the skin is superficially punctured through the droplet with a sterile lancet. Positive and negative control material must be included in the assessment. After 15 minutes, a positive response is indicated by a local weal and flare response 2 mm or more larger than the negative control. A major advantage of skin-prick testing is that patient can clearly see the results, which may be useful in gaining adherence to avoidance measures. Disadvantages include the remote risk of a severe allergic reaction, so resuscitation facilities should be available. Results are unreliable in patients with extensive skin disease. Antihistamines inhibit the magnitude of the response and should be discontinued for at least 3 days before testing; low-dose glucocorticoids do not influence test results. A number of other prescribed medicines can also lead to false-negative results, including amitriptyline and risperidone.

Specific IgE tests
An alternative to skin-prick testing is the quantitation of IgE directed against the suspected allergen. The sensitivity and specificity of specific IgE tests (previously known as radioallergosorbent tests, RAST) are lower than those of skin-prick tests. However, IgE tests may be very useful if skin testing is inappropriate, such as in patients taking antihistamines or those with severe skin disease or dermatographism. They can also be used to test for cross-reactivity — for example, with multiple insect venoms, where component-resolved diagnostics, using recombinant allergens, is increasingly used rather than crude allergen extract. Specific IgE tests can also be used post-mortem to identify allergens responsible for lethal anaphylaxis.

Supervised exposure to allergen
Tests involving supervised exposure to an allergen (allergen challenge) are usually performed in specialist centres on carefully selected patients, and include bronchial provocation testing, nasal challenge, and food or drug challenge. These may be particularly useful in the investigation of occupational asthma or food allergy. Patients can be considered for challenge testing when skin tests and/or IgE tests are negative, as they can be helpful in ruling out allergic disease.

Mast cell tryptase
Measurement of serum mast cell tryptase is extremely useful in investigating a possible anaphylactic event. Ideally, measurements should be made at the time of the reaction following appropriate resuscitation, and 3 hours and 24 hours later. The basis of the test is the fact that circulating levels of mast cell degranulation products rise dramatically to peak 1–2 hours after a systemic allergic reaction. Tryptase is the most stable of these and is easily measured in serum.

Serum total IgE
Serum total IgE measurements are not routinely indicated in the investigation of allergic disease, other than to aid in the interpretation of specific IgE results, as false-positive specific IgEs are common in patients with atopy, who often have a high total IgE level. Although atopy is the most common cause of an elevated total IgE in developed countries, there are many other causes, including parasitic and helminth infections (pp. 299 and 288), lymphoma (p. 961), drug reactions and eosinophilic granulomatosis with polyangiitis (previously known as Churg–Strauss vasculitis; p. 1043). Normal total IgE levels do not exclude allergic disease.

Eosinophilia
Peripheral blood eosinophilia is common in atopic individuals but lacks specificity. Eosinophilia of more than 20% or an absolute eosinophil count over $1.5 \times 10^9/L$ should initiate a search for a non-atopic cause, such as eosinophilic granulomatosis with polyangiitis or parasitic infection (p. 928).

Management
Several approaches can be deployed in the management of allergic individuals, as discussed below.

Avoidance of the allergen
This is indicated in all cases and should be rigorously attempted, with the advice of specialist dietitians and occupational physicians if necessary.

Antihistamines
Antihistamines are useful in the management of allergy as they inhibit the effects of histamine on tissue H1 receptors. Long-acting, non-sedating preparations are particularly useful for prophylaxis.

Glucocorticoids
These are highly effective in allergic disease, and if used topically, adverse effects can be minimised.

Sodium cromoglicate
Sodium cromoglicate stabilises the mast cell membrane, inhibiting release of vasoactive mediators. It is effective as a prophylactic agent in asthma and allergic rhinitis but has no role in management of acute attacks. It is poorly absorbed and therefore ineffective in the management of food allergies.

Antigen-specific immunotherapy
This involves the sequential administration of increasing doses of allergen extract over a prolonged period of time. The mechanism of action is not fully understood but it is highly effective in the prevention of insect venom anaphylaxis and of allergic rhinitis secondary to grass pollen. The traditional route of administration is by subcutaneous injection, which carries a risk of anaphylaxis and should be performed only in specialised centres. Sublingual immunotherapy is also increasingly used. Clinical studies to date do not support the use of allergen immunotherapy for food hypersensitivity, although this is an area of active investigation.

Omalizumab
Omalizumab is a monoclonal antibody directed against IgE; it inhibits the binding of IgE to mast cells and basophils. It is licensed for treatment of refractory chronic spontaneous urticaria and also for severe persistent allergic asthma that has failed to respond to standard therapy (p. 572). The dose and frequency are determined by baseline IgE (measured before the start of treatment) and body weight. It is under investigation for allergic rhinitis but not yet approved for this indication.

Adrenaline (epinephrine)
Adrenaline given by injection in the form of a pre-loaded self-injectable device can be life-saving in the acute management of anaphylaxis (see Box 4.12).
Angioedema

Angioedema is an episodic, localised, non-pitting swelling of submucous or subcutaneous tissues.

Pathophysiology

The causes of angioedema are summarised in Box 4.23. It may be a manifestation of allergy or non-allergic degranulation of mast cells in response to drugs and toxins. In these conditions the main cause is mast cell degranulation with release of histamine and other vasoactive mediators. In hereditary angioedema, the cause is C1 inhibitor deficiency, which causes increased local release of bradykinin. Angiotensin-converting enzyme (ACE) inhibitor-induced angioedema also occurs as the result of increased bradykinin levels due to inhibition of its breakdown.

Clinical features

Angioedema is characterised by soft-tissue swelling that most frequently affects the face (Fig. 4.15) but can also affect the extremities and genitalia. Involvement of the larynx or tongue may cause life-threatening respiratory tract obstruction, and oedema of the intestinal mucosa may cause abdominal pain and distension.

Investigations

Differentiating the mechanism of angioedema is important in determining the most appropriate treatment. A clinical history of allergy or drug exposure can give clues to the underlying diagnosis. If no obvious trigger can be identified, measurement of complement C4 is useful in differentiating hereditary and acquired angioedema from other causes. If C4 levels are low, further investigations should be initiated to look for evidence of C1 inhibitor deficiency.

Management

Management depends on the underlying cause. Angioedema associated with allergen exposure generally responds to antihistamines and glucocorticoids. Following acute management of angioedema secondary to drug therapy, drug withdrawal

Hereditary angioedema

Hereditary angioedema (HAE), also known as inherited C1 inhibitor deficiency, is an autosomal dominant disorder caused by decreased production or activity of C1 inhibitor protein. This complement regulatory protein inhibits spontaneous activation of the classical complement pathway (see Fig. 4.4). It also acts as an inhibitor of the kinin cascade, activation of which increases local bradykinin levels, giving rise to local pain and swelling.

Clinical features

The angioedema in HAE may be spontaneous or triggered by local trauma or infection. Multiple parts of the body may be involved, especially the face, extremities, upper airway and gastrointestinal tract. Oedema of the intestinal wall causes severe abdominal pain and many patients with undiagnosed HAE undergo exploratory laparotomy. The most important complication is laryngeal obstruction, often associated with minor dental procedures, which can be fatal. Episodes of angioedema are self-limiting and usually resolve within 48 hours. Patients with HAE generally present in adolescence but may go undiagnosed for many years. A family history can be identified in 80% of cases. HAE is not associated with allergic diseases and is specifically not associated with urticaria.

Investigations

Acute episodes are accompanied by low C4 levels; a low C4 during an episode of angioedema should therefore trigger further investigation. The diagnosis can be confirmed by measurement of C1 inhibitor levels and function.

Management

Severe acute attacks should be treated with purified C1 inhibitor concentrate or the bradykinin receptor antagonist icatibant. Anabolic steroids, such as danazol, can be used to prevent attacks and act by increasing endogenous production of complement proteins. Tranexamic acid can be helpful as prophylaxis in some patients. Acute episodes of angioedema can continue for a limited period post drug withdrawal. Management of angioedema associated with C1 inhibitor deficiency is discussed below.

Acquired C1 inhibitor deficiency

This rare disorder is clinically indistinguishable from HAE but presents in late adulthood. It is associated with autoimmune and lymphoproliferative diseases. Most cases are due to the development of autoantibodies to C1 inhibitor, but the condition can also be caused by autoantibodies that activate C1. Treatment of the underlying disorder may induce remission of angioedema. As with HAE, a low C4 is seen during acute episodes.

HAE: see p. 926.

Transplantation and graft rejection

Transplantation provides the opportunity for definitive treatment of end-stage organ disease. The major complications are graft rejection, drug toxicity and infection consequent to immunosuppression. Transplant survival continues to improve, as a result of the introduction of less toxic immunosuppressive agents and increased understanding of the processes of transplant rejection. Stem cell transplantation and its complications are discussed on page 936.

Transplant rejection

Solid organ transplantation inevitably stimulates an aggressive immune response by the recipient, unless the transplant is between monozygotic twins. The type and severity of the rejection response is determined by the genetic disparity between the donor and recipient, the immune status of the host and the nature of the tissue transplanted (Box 4.25). The most important genetic determinant

</tbody>
</table>
is the difference between donor and recipient HLA proteins (p. 67). The extensive polymorphism of these proteins means that donor HLA antigens are almost invariably recognised as foreign by the recipient immune system, unless an active attempt has been made to minimise incompatibility.

- **Hyperacute rejection** results in rapid and irreversible destruction of the graft (Box 4.25). It is mediated by pre-existing recipient antibodies against donor HLA antigens, which arise as a result of previous exposure through transplantation, blood transfusion or pregnancy. It is very rarely seen in clinical practice, as the use of screening for anti-HLA antibodies and pre-transplant cross-matching ensures the prior identification of recipient–donor incompatibility.

- **Acute cellular rejection** is the most common form of graft rejection. It is mediated by activated T lymphocytes and results in deterioration in graft function. If allowed to progress, it may cause fever, pain and tenderness over the graft. It is usually amenable to increased immunosuppressive therapy.

- **Acute vascular rejection** is mediated by antibody formed de novo after transplantation. It is more curtailed than the hyperacute response because of the use of intercurrent immunosuppression but it is also associated with reduced graft survival. Aggressive immunosuppressive therapy is indicated and physical removal of antibody through plasmapheresis may be indicated in severe causes. Not all post-transplant anti-donor antibodies cause graft damage; their consequences are determined by specificity and ability to trigger other immune components, such as the complement cascade.

- **Chronic allograft failure**, also known as chronic rejection, is a major cause of graft loss. It is associated with proliferation of transplant vascular smooth muscle, interstitial fibrosis and scarring. The pathogenesis is poorly understood but contributing factors include immunological damage caused by subacute rejection, hypertension, hyperlipidaemia and chronic drug toxicity.

### Investigations

**Pre-transplantation testing**

HLA typing determines an individual’s HLA polymorphisms and facilitates donor–recipient matching. Potential transplant recipients are also screened for the presence of anti-HLA antibodies. The recipient is excluded from receiving a transplant that carries these alleles.

Donor–recipient cross-matching is a functional assay that directly tests whether serum from a recipient (which potentially contains anti-donor antibodies) is able to bind and/or kill donor lymphocytes. It is specific to a prospective donor–recipient pair and is done immediately prior to transplantation. A positive cross-match is a contraindication to transplantation because of the risk of hyperacute rejection.

**Post-transplant biopsy: C4d staining**

C4d is a fragment of the complement protein C4 (see Fig. 4.4). Deposition of C4d in graft capillaries indicates local activation of the classical complement pathway and provides evidence of antibody-mediated damage. This is useful in the early diagnosis of vascular rejection.

### Complications of transplant immunosuppression

Transplant recipients require indefinite treatment with immunosuppressive agents. In general, two or more immunosuppressive drugs are used in synergistic combination in order to minimise adverse effects (Box 4.26). The major complications of long-term immunosuppression are infection and malignancy. The risk of some opportunistic infections may be minimised through the use of prophylactic medication, such as ganciclovir for cytomegalovirus prophylaxis and trimethoprim–sulfamethoxazole for Pneumocystis prophylaxis. Immunisation with killed vaccines is appropriate, although the immune response may be curtailed. Live vaccines should not be given.

The increased risk of malignancy arises because T-cell suppression results in failure to control viral infections associated with malignant transformation. Virus-associated tumours include lymphoma (associated with Epstein–Barr virus), Kaposi’s sarcoma (associated with human herpesvirus 8) and skin tumours (associated with human papillomavirus). Immunosuppression is also linked with a small increase in the incidence of common cancers not associated with viral infection (such as lung, breast and colon cancer), reflecting the importance of T cells in anti-cancer surveillance.

Organ donation

The major problem in transplantation is the shortage of organ donors. Cadaveric organ donors are usually previously healthy individuals who experience brainstem death (p. 211), frequently as a result of road traffic accidents or cerebrovascular events. Even if organs were obtained from all potential cadaveric donors, though, their numbers would be insufficient to meet current needs. An alternative is the use of living donors. Altruistic living donation, usually from close relatives, is widely used in renal transplantation. Living organ donation is inevitably associated with some risk to the donor and it is highly regulated to ensure appropriate appreciation of the risks involved. Because of concerns about coercion and exploitation, non-altruistic organ donation (the sale of organs) is illegal in most countries.

Tumour immunology

Surveillance by the immune system is critically important in monitoring and removing damaged and mutated cells as they arise. The ability of the immune system to kill cancer cells effectively is influenced by tumour immunogenicity and specificity. Many cancer antigens are poorly expressed and specific antigens can mutate, either spontaneously or in response to treatment, which can result in evasion of immune responses. In addition, the inhibitory pathways that are used to maintain self-tolerance and limit collateral tissue damage during antimicrobial immune responses can be co-opted by cancerous cells to evade immune destruction. Recognition and understanding of these immune checkpoint pathways has led to the development of a number of new treatments for cancers that are otherwise refractory to treatment. For example, antibodies to CTLA4, a co-stimulatory molecule normally involved in down-regulation of immune responses, have been licensed for refractory melanoma, and antibodies to PD1 (programmed cell death protein 1) are used in melanoma, non-small-cell lung cancer and renal cell carcinoma. Potential risks include the development of autoimmunity, reflecting the importance of these pathways in the control of self-tolerance.

Further information

The UK Faculty of Public Health defines public health as ‘the science and art of promoting and protecting health and well-being, preventing ill-health and prolonging life through the organised efforts of society’. This definition recognises that there is a collective responsibility for the health of the population that requires partnerships between government, health services and others to promote and protect health and prevent disease. Population health has been defined as ‘the health outcomes of a group of individuals, including the distribution of such outcomes within the group’. Medical doctors can play a role in all these efforts to improve health both through their clinical work and through their support of broader actions to improve public health.

**Global burden of disease and underlying risk factors**

The Global Burden of Disease (GBD) exercise was initiated by the World Bank in 1992, with first estimates appearing in 1993. Regular updated figures have been published since, together with projections of future disease burden. The aim was to produce reliable and internally consistent estimates of disease burden for all diseases and injuries, and to assess their physiological, behavioural and social risk factors, so that this information could be made available to health workers, researchers and policy-makers.

The GBD exercise adopted the metric ‘disability adjusted life year’ (DALY) to describe population health. This combines information about premature mortality in a population (measured as Years of Life Lost from an ‘expected’ life expectancy) and years of life lived with disability (Years of Life lived with Disability, which is weighted by a severity factor). The International Classification of Disease (ICD) rules, which assign one cause to each death, are followed. All estimates are presented by age and sex groups and by regions of the world. Many countries now also report their own national burden of disease data.

**Life expectancy**

Global life expectancy at birth increased from 61.7 years in 1980 to 71.8 years in 2015, an increase of 0.29 years per calendar year. This change is due to a substantial fall in child mortality (mainly caused by common infections), partly offset by rises in mortality from adult conditions such as diabetes and chronic kidney disease. Some areas have not shown these increases in life expectancy in men, often due to war and interpersonal violence.

**Global causes of death and disability**

Box 5.1 shows a ranked list of the major causes of global premature deaths in 2015. Communicable, maternal, neonatal and nutritional causes accounted for about one-quarter of deaths worldwide, down from about one-third in 1990. In contrast, deaths from non-communicable diseases are increasing in importance and now account for about two-thirds of all deaths globally, including about 13 million from ischaemic heart disease and stroke, and about 8 million from cancer. The age-standardised death rates for most diseases globally are falling. However, despite this, the numbers of deaths from many diseases are rising due to global population growth and the change in age structure of the population to older ages, and this is placing an increasing burden on health systems. For a few conditions (e.g. HIV/AIDS, diabetes mellitus and chronic kidney disease), age-standardised death rates continue to rise. Within this overall pattern, significant regional variations exist: for example, communicable, maternal, neonatal and nutritional causes still account for about two-thirds of premature mortality in sub-Saharan Africa.

GBD also provides estimates of disability from disease (Box 5.2). This has raised awareness of the importance of conditions like depression, low back and neck pain, and asthma, which account for a relatively large disease burden but relatively few deaths. This, in turn, has resulted in greater health policy priority being given to these conditions. Since the policy focus in national health systems is increasingly on keeping people healthy rather than only on reducing premature deaths, it is important to have measures of these health outcomes.

It is also essential to recognise that, although these estimates represent the best overall picture of burden of disease, they are based on imperfect data. Nevertheless, the quality of data underlying the estimates and the modelling processes are...
improving over time and provide an increasingly robust basis for evidence-based health planning and priority setting.

**Risk factors underlying disease**

Box 5.3 shows a ranked list of the main risk factors that underlay GBD in 2015 and how this ranking has changed in recent years.

### Social determinants of health

Health emerges from a highly complex interaction between a person’s genetic background and environmental factors (aspects of the physical, biological (microbes), built and social environments, and also distant influences such as the global ecosystem; Fig. 5.1).

**The hierarchy of systems – from molecules to ecologies**

Influences on health exist at many levels and extend beyond the individual to include the family, community, population and ecology. Box 5.4 shows an example of this for determinants of coronary heart disease and demonstrates the importance of considering not only the disease process in a patient but also its context. Health care is not the only determinant – and is usually not the major determinant – of health status in the population. The concept of ‘global health’ recognises the global dimension of health problems, whether these be emerging or pandemic infections or global economic influences on health.

**The life course**

The determinants of health operate over the whole lifespan. Values and behaviours acquired during childhood and adolescence have a profound influence on educational outcomes, job prospects and risk of disease. These can have a strong influence, for example, on whether a young person takes up damaging behaviour like smoking, risky sexual activity and drug misuse. Influences on health can operate even before birth. Low birth weight can lead to higher risk of hypertension and type 2 diabetes in young adults, and of cardiovascular disease in middle age. It has been suggested that under-nutrition during middle to late gestation permanently ‘programs’ cardiovascular and metabolic responses. This ‘life course’ perspective highlights the cumulative effect on health of exposures to illness, adverse environmental conditions and behaviours that damage health.

### Preventive medicine

The complexity of interactions between physical, social and economic determinants of health means successful prevention is often difficult. Moreover, the life-course perspective illustrates that it may be necessary to intervene early in life or even before birth, to prevent important disease later. Successful prevention is likely to require many interventions across the life course and at several levels in the hierarchy of systems. The examples below illustrate this.

Alcohol

Alcohol use is an increasingly important risk factor underlying GBD (see Box 5.3). Reasons for increasing rates of alcohol-related harm vary by place and time but include the falling price of alcohol (in real terms), increased availability and cultural change fostering higher levels of consumption. Public, professional and governmental concern has now led to a minimum price being charged for a unit of alcohol, tightening of licensing regulations and curtailment of some promotional activity in many countries. However, even more aggressive public health measures will be needed to reverse the levels of harm in the population. The approach for individual patients suffering adverse effects of alcohol is described elsewhere (e.g. pp. 1184 and 880).

Smoking

Smoking is one of the top three risk factors underlying GBD (see Box 5.3). It is responsible for a substantial majority of cases of chronic obstructive pulmonary disease (COPD) and lung cancer (pp. 573 and 598), and most smokers die either from these or from ischaemic heart disease. Smoking also causes cancers of the upper respiratory and gastrointestinal tracts, pancreas, bladder and kidney, and increases risks of peripheral vascular disease, stroke and peptic ulceration. Maternal smoking is an important cause of fetal growth retardation. Moreover, there is evidence that passive (‘second-hand’) smoking has adverse effects on cardiovascular and respiratory health.

The decline in smoking in many high-income countries has been achieved not only by warning people of the health risks but also by increasing taxation of tobacco, banning advertising, legislating against smoking in public places and giving support for smoking cessation to maintain this decline. However, smoking rates remain high in many poorer areas and are increasing among young women. In many developing countries, tobacco companies have found new markets and rates are rising.

A complex hierarchy of systems interacts to cause smokers to initiate and maintain their habit. At the molecular and cellular levels, nicotine acts on the nervous system to create dependence and maintain the smoking habit. There are also strong influences at the personal and social level, such as young female smokers being motivated to ‘stay thin’ or ‘look cool’ and peer pressure. Other important influences include cigarette advertising, with the advertising budget of the tobacco industry being much greater than that of health services. Strategies to help individuals stop smoking (such as nicotine replacement therapy, anti-smoking advice and behavioural support) are cost-effective and form an important part of the overall strategy.

Obesity

Obesity is an increasingly important risk factor underlying GBD (see Box 5.3). The weight distribution of almost the whole population is shifting upwards: the slim are becoming less slim while the fat are getting fatter (p. 698). In the UK, this translates into a 1 kg increase in weight per adult per year (on average over the adult population). The current obesity epidemic cannot be explained simply by individual behaviour and poor choice but also requires an understanding of the obesogenic environment that encourages people to eat more and exercise less. This includes the availability of cheap and heavily marketed energy-rich foods, the increase in labour-saving devices (e.g. lifts and remote controls) and the rise in passive transport (cars as opposed to walking, cycling, or walking to public transport hubs). To combat the health impact of obesity, therefore, we not only need to help those who are already obese but also develop strategies that impact on the whole population and reverse the obesogenic environment.

Poverty and affluence

The adverse health and social consequences of poverty are well documented: high birth rates, high death rates and short life expectancy. Typically, with industrialisation, the pattern changes: low birth rates, low death rates and longer life expectancy. Instead of infections, chronic conditions such as heart disease dominate in an older population. Adverse health consequences of excessiveaffluence are also becoming apparent. Despite experiencing sustained economic growth for the last 50 years, people in many industrialised countries are not growing any happier and the litany of socioeconomic problems – crime, congestion, inequality – persists.

Many countries are now experiencing a ‘double burden’. They have large populations still living in poverty who are suffering from problems such as diarrhoea and malnutrition, alongside affluent populations (often in cities) who suffer from chronic illness such as diabetes and heart disease.

Atmospheric pollution

Emissions from industry, power plants and motor vehicles of sulphur oxides, nitrogen oxides, respirable particles and metals are severely polluting cities and towns in Asia, Africa, Latin America and Eastern Europe. Burning of fossil and biomass fuels, with production of short-lived carbon pollutants (SLCPs – methane, ozone, black carbon and hydrofluorocarbons), contributes to increased death rates from respiratory and cardiovascular disease in vulnerable adults, such as those with established respiratory disease and the elderly, while children experience an increase in bronchitic symptoms. Developing countries also suffer high rates of respiratory disease as a result of indoor pollution caused mainly by heating and cooking using solid biomass fuels.

Climate change and global warming

Climate change is arguably the world’s most important environmental health issue. A combination of habitat destruction and increased production of carbon dioxide and SLCPs, caused primarily by human activity, seems to be the main cause. The temperature of the globe is rising, and if current trends continue, warming by 4°C is predicted by 2050. The climate is being affected, putting millions of people at risk of rising sea levels, flooding, droughts and failed crops. These have already claimed millions of lives during the past 20 years and have adversely affected the lives of many more. The economic costs of property damage and the impact on agriculture, food supplies and prosperity have also been substantial. Global warming will also include changes in the geographical range of some vector-borne infectious diseases. Currently, politicians cannot agree an effective framework of actions to tackle the problem, but reducing emissions of CO₂ and SLCPs is essential.

Principles of screening

Screening is the application of a test to a large number of asymptomatic people with the aim of reducing morbidity or mortality from a disease. The World Health Organisation (WHO)
has identified a set of (Wilson and Jungner) criteria to guide health systems in deciding when it is appropriate to implement screening programmes. The essential criteria are:

- Is the disease an important public health problem?
- Is there a suitable screening test available?
- Is there a recognisable latent or early stage?
- Is there effective treatment for the disease at this stage that improves prognosis?

A suitable screening test is one that is cheap, acceptable, easy to perform and safe, and gives a valid result in terms of sensitivity and specificity (p. 4). Screening programmes should always be evaluated in trials so that robust evidence is provided in favour of their adoption. These evaluations are prone to several biases – self-selection bias, lead-time bias and length bias – and these need to be accounted for in the analysis. Examples of large-scale programmes in the UK include breast, colorectal and cervical cancer national screening programmes and a number of screening tests carried out in pregnancy and in the newborn, such as the:

- diabetic eye screening programme
- fetal anomaly screening programme
- infectious diseases in pregnancy screening programme
- newborn and infant physical examination screening programme
- newborn blood spot screening programme
- newborn hearing screening programme
- sickle-cell and thalassaemia screening programme.

These are illustrated in Figure 5.2.

Problems with screening include:

- over-diagnosis (of a disease that would not have come to attention on its own or would not have led to death)
- false reassurance
- diversion of resources from investments that could control the disease more cost-effectively.

An example of these problems is the use of prostate-specific antigen (PSA) testing as a screening test for the diagnosis of prostate cancer (p. 439).

### Epidemiology

Epidemiologists study disease in free-living humans, seeking to describe patterns of health and disease and to understand how different exposures cause or prevent disease (Box 5.5).

Chronic diseases and risk factors (e.g. smoking, obesity etc.) are often described in terms of their prevalence. A prevalence is simply a proportion: e.g. the prevalence of diabetes in people aged 80 and older in developed countries is around 10%.

Events such as deaths, hospitalisations and first occurrences of a disease are described using incidence rates: e.g. if there are 100 new cases of a disease in a single year in a population of 1000, the incidence rate is 105 per 1000 person-years, not 100, because of the effect of ‘person-time’. Person-time is the sum of the total ‘exposed’ time for the population and in this example is 950 person-years. The reason person-time is less than 1000 is that 100 people experienced the event. These 100 people are assumed to have had an event, on average, halfway through the time period, removing $100 \times 0.5$ person-years from the exposure time (as it is not possible to have a first occurrence of a disease twice). Hence, the incidence per 1000 person-years is 105, not 100.

### 5.5 Calculation of risk using descriptive epidemiology

<table>
<thead>
<tr>
<th>Prevalence</th>
<th>The ratio of the number of people with a longer-term disease or condition, at a specified time, to the number of people in the population</th>
</tr>
</thead>
<tbody>
<tr>
<td>Incidence</td>
<td>The number of events (new cases or episodes) occurring in the population at risk during a defined period of time</td>
</tr>
<tr>
<td>Attributable risk</td>
<td>The difference between the risk (or incidence) of disease in exposed and non-exposed populations</td>
</tr>
<tr>
<td>Attributable fraction</td>
<td>The ratio of the attributable risk to the incidence</td>
</tr>
<tr>
<td>Relative risk</td>
<td>The ratio of the risk (or incidence) in the exposed population to the risk (or incidence) in the non-exposed population</td>
</tr>
</tbody>
</table>

A similar measure is the cumulative incidence or risk, which is the number of new cases as a proportion of the total people at risk at the beginning of the exposure time. If, in the example above, the same 1000 people were observed for a year (i.e. with no one joining or leaving the group), then the 1-year risk is 10% (100/1000). The time period should always be specified.

These rates and proportions are used to describe how diseases (and risk factors) vary according to time, person and place. Temporal variation may occur seasonally (e.g. malaria occurs in the wet season but not the dry) or as longer-term ‘secular’ trends (e.g. malaria may re-emerge due to drug resistance). Person comparisons include age, sex, socioeconomic status, employment, and lifestyle characteristics. Place comparisons include the local environment (e.g. urban versus rural) and international comparisons.

### Understanding causes and effect

Epidemiological research complements that based on animal, cell and tissue models, the findings of which do not always translate to humans. For example, only a minority of drug discoveries from laboratory research are effective when tested in people.

However, differentiating causes from mere non-causal associations is a considerable challenge for epidemiology. This is because while laboratory researchers can directly manipulate conditions to isolate and understand causes, such approaches are impossible in free-living populations. Epidemiologists have developed a different approach, based around a number of study designs (Box 5.6). Of these, the clinical trial is closest to the laboratory experiment. An early example of a clinical trial is shown in Figure 5.3, along with ‘effect measures’, which are used to quantify the difference in rates and risks.

In clinical trials, patients are usually allocated randomly to treatments so that, on average, groups are similar, apart from the intervention of interest. Nevertheless, for any particular trial, especially a small trial, the laws of probability mean that differences can and do occur by chance. Poorly designed or executed trials can also limit comparability between groups. Allocation may not be truly random (e.g. because of inadequate concealment of the randomisation sequence), and there may...

Pregnancy
- Blood for sickle cell and thalassaemia
- Blood for syphilis, hepatitis B and HIV as early as possible, or at any stage of the pregnancy, including labour
- Blood for haemoglobin, group, Rhesus and antibodies as early as possible, or as soon as a woman arrives for care, including labour
- Early pregnancy scan to support T21, T18 and T13 screening
- Detailed ultrasound scan for structural abnormalities, including T18 and T13
- Follow-up DE screen for women with type 1 or 2 diabetes found to have diabetic retinopathy
- Further DE screen for women with type 1 or 2 diabetes

Newborn
- Hepatitis B vaccination ± immunoglobulin within 24 hours
- Newborn physical examination by 72 hours
- Newborn blood spot screens (ideally on day 5) for sickle cell disease (SCD), cystic fibrosis (CF), congenital hypothyroidism (CHT) and inherited metabolic diseases (PKU, MCADD, MSUD, IVA, GA1 and HCU).
- NB: babies who missed the screen can be tested up to 1 year (except CF offered up to 8 weeks)

Key
- T21, T18, T13 and fetal anomaly ultrasound
- Sickle cell and thalassaemia
- Newborn and infant physical examination
- Newborn hearing
- Newborn blood spot
- Infectious diseases in pregnancy
- Diabetic eye

Fig. 5.2 UK NHS Pregnancy and Newborn Screening Programmes: optimum times for testing. (GA1 = glutaric aciduria type 1; HCU = homocystinuria; IVA = isovaleric acidemia; MCADD = medium-chain acyl-CoA dehydrogenase deficiency; MSUD = maple syrup urine disease; PKU = phenylketonuria; T13, 18, 21 = trisomy 13, 18 and 21) Based on Version 8.1, March 2016, Gateway ref: 2014696, Public Health England.
Epidemiologists therefore seek to minimize bias and confounding by good study analysis and design. They subsequently make causal inferences by balancing the probability that an observed association has been caused by chance, bias and/or confounding against the alternative probability that the relationship is causal. This weighing-up requires an understanding of the frequency and importance of different sources of bias and confounding, as well as the scientific rationale of the putative causal relationship. It was this approach, collectively and over a number of years, that settled the fact that smoking causes lung cancer and, subsequently, heart disease.

As patients pass through health and social care systems, data are recorded concerning their family background, lifestyle and disease states, which is of potential interest to health-care organisations seeking to deliver services, policy-makers concerned with improving health, scientific researchers trying to understand health, and also pharmaceutical and other commercial organisations aiming to identify markets.

Epidemiological study designs

<table>
<thead>
<tr>
<th>Design</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clinical trial</td>
<td>Enrols a sample from a population and compares outcomes after randomly allocating patients to an intervention</td>
<td>Medical Research Council (MRC) Streptomycin Trial – demonstrated effectiveness of streptomycin in tuberculosis</td>
</tr>
<tr>
<td>Cohort</td>
<td>Enrols a sample from a population and compares outcomes according to exposures</td>
<td>Framingham Study – identified risk factors for cardiovascular disease</td>
</tr>
<tr>
<td>Case–control</td>
<td>Enrols cases with an outcome of interest and controls without that outcome and compares exposures between the groups</td>
<td>Doll R, Hill AB. Smoking and carcinoma of the lung. British Medical Journal 1950 – demonstrated that smoking caused lung cancer</td>
</tr>
<tr>
<td>Cross-sectional</td>
<td>Enrols a cross-section (sample) of people from the population of interest; obtains data on exposures and outcomes</td>
<td>World Health Organisation Demographic and Health Survey – captures risk factor data in a uniform way across many countries</td>
</tr>
</tbody>
</table>

Fig. 5.3 An example of a clinical trial: streptomycin versus bed rest in tuberculosis. Both prevalences and risks are, in fact, proportions, and are therefore frequently expressed as odds. The reasons for doing so are beyond the scope of this text.

Effect measures

<table>
<thead>
<tr>
<th>Measure</th>

<td>4.6</td>
</tr>
</tbody>
</table>

be systematic differences (biases) in the way people allocated to different groups are treated or studied.

Such biases also occur in observational epidemiological study designs, such as cohort, case–control and cross-sectional studies (Box 5.6). These designs are also much more subject to the problem of confounding than are randomised trials.

Confounding is where the relationship between an exposure and outcome of interest is confused by the presence of some other causal factor. For example, coffee consumption may be associated with lung cancer because smoking is more common among coffee-drinkers. Here, smoking is said to confound the association between coffee and lung cancer.

Despite these limitations, for most causes of diseases, randomised controlled trials are not feasible because of ethical, or more often practical, considerations. Epidemiologists therefore seek to minimize bias and confounding by good study analysis and design. They subsequently make causal inferences by balancing the probability that an observed association has been caused by chance, bias and/or confounding against the alternative probability that the relationship is causal. This weighing-up requires an understanding of the frequency and importance of different sources of bias and confounding, as well as the scientific rationale of the putative causal relationship. It was this approach, collectively and over a number of years, that settled the fact that smoking causes lung cancer and, subsequently, heart disease.

Health data/informatics

As patients pass through health and social care systems, data are recorded concerning their family background, lifestyle and disease states, which is of potential interest to health-care organisations seeking to deliver services, policy-makers concerned with improving health, scientific researchers trying to understand health, and also pharmaceutical and other commercial organisations aiming to identify markets.

There is a long tradition of maintaining health information systems. In most countries, registration of births and deaths is required by law, and in the majority, the cause of death is also recorded (Fig. 5.4). There are many challenges in ensuring such data are useful, especially for comparisons across time and place:

- A system of standard terminologies is needed, such as the WHO International Classification of Diseases (ICD-10), which provides a list of diagnostic codes attempting to cover every diagnostic entity.
- These terms must be understood to refer to the same, or at least similar, diseases in different places.
- Access to diagnostic skill and facilities is required.
- Standard protocols for assigning clinical diagnoses to ICD-10 codes are needed.
- Robust quality control processes are needed to maintain some level of data completeness and accuracy.

Many countries employ similar systems for hospitalisations, to allow recovery of health-care utilisation costs or to manage and plan services. Similar data are rarely collected for community-based health care, nor are detailed data on health-care processes generally included in national data systems. Consequently, there has been considerable interest in using data from information technology systems used to deliver care, such as electronic
Data from such systems are, of course, much less structured than those obtained from vital registrations. Moreover, the completeness of such data depends greatly on local patterns of health-care utilisation, as well as how clinicians and others use information technology systems within different settings. As such, deriving useful, unbiased information from such data is a considerable challenge.

Much of the discipline of health informatics is concerned with addressing this challenge. One approach has been to develop comprehensive standard classification systems such as SNOMED-CT, “a standardised, multilingual vocabulary of terms relating to the care of the individual”, which has been designed for electronic health-care records.

An alternative has been to use statistical methods such as natural language processing to derive information automatically from free text (such as culling diagnoses from radiological reports), or to employ ‘machine learning’, in which software algorithms are applied to data in order to derive useful insights. Such approaches are suited to large, messy data where the costs of systematisation would be prohibitive. It is likely that such innovations will, over the coming years, provide useful information to complement that obtained from more traditional health information systems.

</table>
‘Infection’ in its strict sense describes the situation where microorganisms or other infectious agents become established in the host organism’s cells or tissues, replicate, cause harm and induce a host response. If a microorganism survives and replicates on a mucosal surface without causing harm or illness, the host is said to be ‘colonised’ by that organism. If a microorganism survives and lies dormant after invading host cells or tissues, infection is said to be ‘latent’. When the infectious agent, or the host response to it, is sufficient to cause illness or harm, then the process is termed an ‘infectious disease’. Most pathogens (infectious agents that can cause disease) are microorganisms but some are multicellular organisms. The manifestations of disease may aid pathogen dissemination (e.g. diarrhoea).

The term ‘infection’ is often used interchangeably with ‘infectious disease’ but not all infections are ‘infectious’, i.e. transmissible from person to person. Infectious diseases transmitted between hosts are called communicable diseases, whereas those caused by organisms that are already colonising the host are described as endogenous. The distinction is blurred in some situations, including health care-associated infections such as meticillin-resistant Staphylococcus aureus (MRSA) or Clostridium difficile infection (CDI), in which colonisation precedes infection but the colonising bacteria may have been recently transmitted between patients. The chain of infection (Fig. 6.1) describes six essential elements for communicable disease transmission.

Despite dramatic advances in hygiene, immunisation and antimicrobial therapy, infectious agents still cause a massive burden of disease worldwide. Key challenges remain in tackling infection in resource-poor countries. Microorganisms are continually mutating and evolving; the emergence of new infectious agents and antimicrobial-resistant microorganisms is therefore inevitable. This chapter describes the biological and epidemiological principles of infectious diseases and the general approach to their prevention, diagnosis and treatment. Specific infectious diseases are described in Chapters 11–13 and many of the organ-based chapters.

### Infectious agents

The concept of an infectious agent was established by Robert Koch in the 19th century (Box 6.1). Although fulfilment of ‘Koch’s postulates’ became the standard for the definition of an infectious agent, they do not apply to uncultivable organisms (e.g. Mycobacterium leprae, Tropheryma whipplei) or members of the normal human flora (e.g. Escherichia coli, Candida spp.). The following groups of infectious agents are now recognised.

#### Viruses

Viruses are incapable of independent replication. Instead, they subvert host cellular processes to ensure synthesis of their nucleic acids and proteins. Viruses’ genetic material (the genome) consists of single- or double-stranded DNA or RNA. Retroviruses transcribe their RNA into DNA in the host cell by reverse transcription. An antigenically unique protein coat (capsid) encloses the genome, and together these form the nucleocapsid. In many viruses, the nucleocapsid is packaged within a lipid envelope. Enveloped viruses are less able to survive in the environment and are spread by respiratory, sexual or blood-borne routes, including arthropod-based transmission. Non-enveloped viruses survive better in the environment and are predominantly transmitted by faecal–oral or, less often, respiratory routes. A generic virus life cycle is shown in Figure 6.2. A virus that infects a bacterium is a bacteriophage (phage).

#### Prokaryotes: bacteria (including mycobacteria and actinomycetes)

Prokaryotic cells are capable of synthesising their own proteins and nucleic acids, and are able to reproduce autonomously, although they lack a nucleus. The bacterial cell membrane is bounded by a peptidoglycan cell wall, which is thick (20–80 nm) in Gram-positive organisms and thin (5–10 nm) in Gram-negative ones. The Gram-negative cell wall is surrounded by an outer membrane containing lipopolysaccharide. Genetic information is contained within a chromosome but bacteria may also contain rings of extra-chromosomal DNA, known as plasmids, which can be transferred between organisms, without cells having to divide. Bacteria may be embedded in a polysaccharide capsule.
Infectious agents

Eukaryotes: fungi, protozoa and helminths

Eukaryotic cells contain membrane-bound organelles, including nuclei, mitochondria and Golgi apparatus. Pathogenic eukaryotes are unicellular (e.g., fungi, protozoa) or complex multicellular organisms (e.g., nematodes, trematodes and cestodes, p. 288).

Fig. 6.2 A generic virus life cycle. Life cycle components common to most viruses are host cell attachment and penetration, virus uncoating, nucleic acid and protein synthesis, virus assembly and release. Virus release is achieved either by budding, as illustrated, or by lysis of the cell membrane. Life cycles vary between viruses.
Fig. 6.3 Flow chart for bacterial identification, including Gram film appearances on light microscopy (×100). (MALDI-TOF-MS = matrix-assisted laser desorption/ionisation time-of-flight mass spectroscopy)

Fig. 6.4 Beta-haemolytic streptococci (A) and alpha-haemolytic streptococci (B) spread on each half of a blood agar plate (backlit). This image is half life size, ×0.5. Beta-haemolysis renders the agar transparent around the colonies (A) and alpha-haemolysis imparts a green tinge to the agar (B).

Fungi exist as either moulds (filamentous fungi) or yeasts. Dimorphic fungi exist in either form, depending on environmental conditions (see Fig. 11.59, p. 300). The fungal plasma membrane differs from the human cell membrane in that it contains the sterol, ergosterol. Fungi have a cell wall made up of polysaccharides, chitin and mannoproteins. In most fungi, the main structural component of the cell wall is β-1,3-D-glucan, a glucose polymer. These differences from mammalian cells are important because they offer useful therapeutic targets.

Protozoa and helminths are often referred to as parasites. Many parasites have complex multi-stage life cycles, which involve animal and/or plant hosts in addition to humans.

Prions

Although prions are transmissible and have some of the characteristics of infectious agents, they are not microorganisms and are not diagnosed in microbiology laboratories. Prions are covered on page 250.

Normal microbial flora

The human body is colonised by large numbers of microorganisms (collectively termed the human microbiota). These colonising
Normal microbial flora

• 103

bacteria, also referred to as the ‘normal flora’, are able to survive and replicate on skin and mucosal surfaces. The gastrointestinal tract and the mouth are the two most heavily colonised sites in the body and their microbiota are distinct, in both composition and function. Knowledge of non-sterile body sites and their normal flora is required to inform microbiological sampling strategies and interpret culture results (Fig. 6.5).

The microbiome is the total burden of microorganisms, their genes and their environmental interactions, and is now recognised to have a profound influence over human health and disease. Maintenance of the normal flora is beneficial to health. For example, lower gastrointestinal tract bacteria synthesise and excrete vitamins (e.g. vitamins K and B12); colonisation with normal flora confers ‘colonisation resistance’ to infection with pathogenic organisms by altering the local environment (e.g. lowering pH), producing antibacterial agents (e.g. bacteriocins (small antimicrobial peptides/proteins), fatty acids and metabolic waste products), and inducing host antibodies that cross-react with pathogenic organisms.

Conversely, normally sterile body sites must be kept sterile. The mucociliary escalator transports environmental material deposited in the respiratory tract to the nasopharynx. The urethral sphincter prevents flow from the non-sterile urethra to the sterile bladder. Physical barriers, including the skin, lining of the gastrointestinal tract and other mucous membranes, maintain sterility of the submucosal tissues, blood stream and peritoneal and pleural cavities, for example.

The normal flora contribute to endogenous disease mainly by translocation to a sterile site but excessive growth at the ‘normal’ site (overgrowth) can also cause disease. Overgrowth is exemplified by dental caries, vaginal thrush and ‘blind loop’ syndrome (p. 806). Translocation results from spread along a surface or penetration through a colonised surface, e.g. urinary tract infection caused by perineal/enteric flora, and surgical site infections, particularly of prosthetic materials, caused by skin flora such as staphylococci. Normal flora also contribute to disease by cross-infection, in which organisms that are colonising one individual cause disease when transferred to another, more susceptible, individual.

The importance of limiting perturbations of the microbiota by antimicrobial therapy is increasingly recognised. Probiotics are microbes or mixtures of microbes that are given to a patient to prevent or treat infection and are intended to restore a beneficial profile of microbiota. Although probiotics have been used in a number of settings, whether they have demonstrable clinical benefits remains a subject of debate.
**Host–pathogen interactions**

‘Pathogenicity’ is the capability of an organism to cause disease and ‘virulence’ is the extent to which a pathogen is able to cause disease. Pathogens produce proteins and other factors, termed virulence factors, which contribute to disease.

- **Primary pathogens** cause disease in a proportion of individuals to whom they are exposed, regardless of the host’s immunological status.
- **Opportunistic pathogens** cause disease only in individuals whose host defences are compromised, e.g. by an intravascular catheter, or when the immune system is compromised, by genetic susceptibility or immunosuppressive therapy.

### Characteristics of successful pathogens

Successful pathogens have a number of attributes. They compete with host cells and colonising flora by various methods, including sequestration of nutrients and production of bacteriocins. Motility enables pathogens to reach their site of infection, often sterile sites that colonising bacteria do not reach, such as the distal airway. Many microorganisms, including viruses, use ‘adhesins’ to attach to host cells initially. Some pathogens can invade through tissues. Many bacterial and fungal infections form ‘biofilms’. After initial adhesion to a host surface, bacteria multiply in biofilms to form complex three-dimensional structures surrounded by a matrix of host and bacterial products that afford protection to the colony and limit the effectiveness of antimicrobials. Biofilms forming on man-made medical devices such as vascular catheters and require further study.

Pathogenic bacteria express different genes, depending on environments, including after phagocytosis by macrophages. Genetic diversity enhances the pathogenic capacity of bacteria. Some virulence factor genes are found on plasmids or in phages and are exchanged between different strains or species. The ability to acquire genes from the gene pool of all strains of the species (the ‘bacterial supragenome’) increases diversity and the potential for pathogenicity. Viruses exploit their rapid reproduction and potential to exchange nucleic acid with host cells to enhance diversity. Once a strain acquires a particularly effective combination of virulence genes, it may become an epidemic strain, accounting for a large subset of infections in a particular region. This phenomenon accounts for influenza pandemics (see Box 6.3).

### The host response

Innate and adaptive immune and inflammatory responses, which humans use to control the normal flora and respond to pathogens, are reviewed in Chapter 4.

### Pathogenesis of infectious disease

The harmful manifestations of infection are determined by a combination of the virulence of the organism and the host response to infection. Despite the obvious benefits of an intact host response, an excessive response is undesirable. Cytokines and antimicrobial factors contribute to tissue injury at the site of infection, and an excessive inflammatory response may lead to hypotension and organ dysfunction (p. 196). The contribution of the immune response to disease manifestations is exemplified by the immune reconstitution inflammatory syndrome (IRIS). This is seen, for example, in human immunodeficiency virus (HIV) infection, post-transplantation neutropenia or tuberculosis (which causes suppression of T-cell function); there is a paradoxical worsening of the clinical condition as the immune dysfunction is corrected, caused by an exuberant but dysregulated inflammatory response.

#### The febrile response

Thermoregulation is altered in infectious disease, which may cause both hyperthermia (fever) and hypothermia. Fever is mediated mainly by ‘pyrogenic cytokines’ (e.g. interleukins IL-1 and IL-6, and tumour necrosis factor alpha (TNF-α)), which are released in response to various immunological stimuli including activation of pattern recognition receptors (PRRs) by microbial pyrogens (e.g. lipopolysaccharide) and factors released by injured cells. Their ultimate effect is to induce the synthesis of prostaglandin E₂, which binds to specific receptors in the preoptic nucleus of the hypothalamus (thermoregulatory centre), causing the core temperature to rise.

Rigors are a clinical symptom (or sign if they are witnessed) characterised by feeling very cold (‘chills’) and uncontrollable shivering, usually followed by fever and sweating. Rigors occur when the thermoregulatory centre attempts to correct a core temperature to a higher level by stimulating skeletal muscle activity and shaking.

There are data to support the hypothesis that raised body temperature interferes with the replication and/or virulence of pathogens. The mechanisms and possible protective role of infection-driven hyperthermia, however, are poorly understood, and require further study.

Investigation of infection

The aims of investigating a patient with suspected infection are to confirm the presence of infection, identify the specific pathogen(s) and identify its susceptibility to specific antimicrobial agents in order to optimise therapy. The presence of infection may be suggested by identifying proteins that are produced in response to pathogens as part of the innate immune and acute phase responses (p. 70). Pathogens may be detected directly (e.g. by culturing a normally sterile body site) or their presence may be inferred by identifying the host response to the organism, (‘indirect detection’, Box 6.4). Careful sampling increases the likelihood of diagnosis (Box 6.5). Culture results must be interpreted in the context of the normal flora at the sampled site (see Fig. 6.5). The extent to which a microbiological test result supports or excludes a particular diagnosis depends on its statistical performance (e.g. sensitivity, specificity, positive and negative predictive value, p. 4). Sensitivity and specificity vary according to the time between infection and testing, and positive and negative predictive values depend on the prevalence of the condition in the test population. The complexity of test interpretation is illustrated in Figure 6.8 below, which shows the ‘windows of opportunity’ afforded by various testing methods. Given this complexity, effective communication between the clinician and the microbiologist is vital to ensure accurate test interpretation.

Direct detection of pathogens

Some direct detection methods provide rapid results and enable detection of organisms that cannot be grown easily on artificial culture media, such as detection of organisms that cannot be grown easily on artificial culture media, such as Chlamydia spp.; they can also provide information on antimicrobial sensitivity, e.g. Mycobacterium tuberculosis.

Detection of whole organisms

Whole organisms are detected by examination of biological fluids or tissue using a microscope.

- **Bright field microscopy** (in which the test sample is interposed between the light source and the objective lens) uses stains to enhance visual contrast between the organism and its background. Examples include Gram staining of bacteria and Ziehl–Neelsen or auramine staining of acid- and alcohol-fast bacilli (AABF) in tuberculosis (the latter requires an ultraviolet light source). In histopathological examination of tissue samples, multiple stains are used to demonstrate not only the presence of microorganisms but also features of disease pathology.
- **Dark field microscopy** (in which light is scattered to make organisms appear bright on a dark background) is used, for example, to examine genital chancre fluid in suspected syphilis.
- **Electron microscopy** may be used to examine stool and vesicle fluid to detect enteric and herpesviruses, respectively, but its use has largely been supplanted by nucleic acid detection (see below).
- **Flow cytometry** can be used to analyse liquid samples (e.g. urine) for the presence of particles based on properties such as size, impedance and light scatter. This technique can detect bacteria but may misidentify other particles as bacteria too.

### 6.5 How to provide samples for microbiological sampling

#### Communicate with the laboratory
- Discuss samples that require processing urgently or that may contain hazardous or unusual pathogens with laboratory staff before collection
- Communication is key to optimising microbiological diagnosis. If there is doubt about any aspect of sampling, it is far better to discuss it with laboratory staff beforehand than to risk diagnostic delay by inappropriate sampling or sample handling

#### Take samples based on a clinical diagnosis
- Sampling in the absence of clinical evidence of infection is rarely appropriate (e.g. collecting urine, or sputum for culture)

#### Use the correct container
- Certain tests (e.g. nucleic acid and antigen detection tests) require proprietary sample collection equipment

#### Follow sample collection procedures
- Failure to follow sample collection instructions precisely can result in false-positive (e.g. contamination of blood culture samples) or false-negative (e.g. collection of insufficient blood for culture) results

#### Label sample and request form correctly
- Label sample containers and request forms according to local policies, with demographic identifiers, specimen type and time/date collected
- Include clinical details on request forms
- Identify samples carrying a high risk of infection (e.g. blood liable to contain a blood-borne virus) with a hazard label

#### Use appropriate packaging
- Close sample containers tightly and package securely (usually in sealed plastic bags)
- Attach request forms to samples but not in the same compartment (to avoid contamination, should leakage occur)

#### Manage storage and transport
- Transport samples to the microbiology laboratory quickly
- If pre-transport storage is required, conditions (e.g. refrigeration, incubation, storage at room temperature) vary with sample type
- Notify the receiving laboratory prior to arrival of unusual or urgent samples, to ensure timely processing
Detection of components of organisms

Components of microorganisms detected for diagnostic purposes include nucleic acids, cell wall molecules, toxins and other antigens. Commonly used examples include *Legionella pneumophila* serogroup 1 antigen in urine and cryptococcal polysaccharide in cerebrospinal fluid (CSF). Most antigen detection methods are based on in vitro binding of specific antigen/antibody and are described below. Other methods may be used, such as tissue culture cytotoxicity assay for *C. difficile* toxin. In toxin-mediated disease, detection of toxin may be of greater relevance than identification of the organism itself (e.g. stool *C. difficile* toxin).

Nucleic acid amplification tests

In a nucleic acid amplification test (NAAT), specific sequences of microbial DNA and RNA are identified using a nucleic acid primer that is amplified exponentially by enzymes to generate multiple copies of a target nucleotide sequence. The most commonly used amplification method is the polymerase chain reaction (PCR; see Fig. 3.11, p. 53). Reverse transcription (RT) PCR is used to detect RNA from RNA viruses (e.g. hepatitis C virus and HIV-1). The use of fluorescent labels in the reaction enables ‘real-time’ detection of amplified DNA; quantification is based on the principle that the time taken to reach the detection threshold is proportional to the initial number of copies of the target nucleic acid sequence. In multiplex PCR, multiple primer pairs are used to enable detection of several different organisms at once.

Determination of nucleotide sequences in a target gene(s) can be used to assign microorganisms to specific strains, which may be relevant to treatment and/or prognosis (e.g. in hepatitis C infection, p. 877). Genes that are relevant to pathogenicity (such as toxin genes) or antimicrobial resistance can also be detected; for example, the *mecA* gene is used to screen for MRSA.

NAATs are the most sensitive direct detection methods and are also relatively rapid. They are used widely in virology, where the possibility of false-positive results from colonising or contaminating organisms is remote, and are applied to blood, respiratory samples, stool and urine. In bacteriology, PCR is used to examine CSF, blood, tissue and genital samples, and multiplex PCR is being developed for use in faeces. PCR is particularly helpful for microorganisms that cannot be readily cultured, e.g. *Tropheryma whipplei*, and is being used increasingly in mycology and parasitology.

Culture

Microorganisms may be both detected and further characterised by culture from clinical samples (e.g. tissue, swabs and body fluids).

- **Ex vivo culture** (tissue or cell culture) was widely used in the isolation of viruses but has been largely supplanted by NAAT.
- **In vitro culture** (in artificial culture media) of bacteria and fungi is used to confirm the presence of pathogens, allow identification, test antimicrobial susceptibility and subtype the organism for epidemiological purposes.

Culture has its limitations: results are not immediate, even for organisms that are easy to grow, and negative cultures rarely exclude infection. Organisms such as *Mycobacterium tuberculosis* are slow-growing, typically taking at least 2 weeks, even in rapid-culture systems. Certain organisms, such as *Mycobacterium leprae* and *Tropheryma whipplei*, cannot be cultivated on artificial media, and others (e.g. *Chlamydia* spp. and viruses) grow only in culture systems, which are slow and labour-intensive.

Blood culture

The terms ‘bacteraemia’ and ‘fungaemia’ describe the presence of bacteria and fungi in the blood. ‘Blood-stream infection’ (p. 225) is the association of bacteraemia/fungaemia with clinical evidence of infection. The presence of bacteraemia/fungaemia can be determined by inoculating a liquid culture medium with freshly drawn blood, which is then incubated in a system that monitors it constantly for growth of microorganisms (e.g. by detecting products of microbial respiration using fluorescence; Fig. 6.6). If growth is detected, organisms are identified and sensitivity testing is performed. Traditionally, identification has been achieved by Gram stain appearance and biochemical reactions. However, matrix-assisted laser desorption/ionisation time-of-flight mass spectroscopy (MALDI-TOF-MS; see Box 6.2) is being used increasingly to identify organisms. MALDI-TOF-MS produces a profile of proteins of different sizes from the target microorganism and uses databases of such profiles to identify the organism (Fig. 6.7). It is rapid and accurate. Taking multiple blood samples for culture at different times allows differentiation of transient (one or two positive samples) and persistent (majority are positive) bacteraemia. This can be clinically important in the identification of the source of infection (p. 530).

Indirect detection of pathogens

Tests may be used to detect the host’s immune (antibody) response to a specific microorganism, and can enable the diagnosis of infection with organisms that are difficult to detect by other methods or are no longer present in the host. The term ‘serology’ describes tests carried out on serum and includes both antigen (direct) and antibody (indirect) detection.

Antibody detection

Organism-specific antibody detection is applied mainly to blood (Fig. 6.8). Results are typically expressed as titres: that is, the reciprocal of the highest dilution of the serum at which antibody is detectable (for example, detection at serum dilution of 1:64 gives a titre of 64). ‘Seroconversion’ is defined as either a change from negative to positive detection or a fourfold rise in titre between acute and convalescent serum samples. An acute sample is usually taken during the first week of disease and the convalescent sample 2–4 weeks later. Earlier diagnosis can be achieved by detection of immunoglobulin M (IgM) antibodies, which are produced early in infection (p. 68). A limitation of these tests is that antibody production requires a fully functional host immune system, so there may be false-negative results in immunocompromised patients. Also, other than in chronic infections and with IgM detection, antibody tests usually provide a retrospective diagnosis.

Antibody detection methods are described below (antigen detection methods are also described here as they share similar methodology).

**Enzyme-linked immunosorbent assay**

The principles of the enzyme-linked immunosorbent assay (ELISA, EIA) are illustrated in Figure 6.9. These assays rely on linking
Immunofluorescence assays

Indirect immunofluorescence assays (IFAs) detect antibodies by incubating a serum sample with immobilised antigen (e.g. cells known to be infected with virus on a glass slide); any virus-specific antibody present in the serum binds to antigen and is then detected using a fluorescent-labelled anti-human immunoglobulin (‘secondary’ antibody). Fluorescence is visualised using a microscope. This method can also detect organisms in clinical samples (usually tissue or centrifuged cells) using a specific antibody in place of immobilised antigen to achieve capture.

Complement fixation test

In a complement fixation test (CFT), patient serum is heat-treated to inactivate complement and mixed with the test antigen. Any specific antibody in the serum will complex with the antigen and complement is then added to the reaction. If antigen–antibody complex forms, it will be detected using a specific antibody to complement fragment C3 with which it complexes. C3 has an enzyme that generates a colour change on exposure to a chromogenic substrate. Various configurations allow detection of antigens or specific subclasses of immunoglobulin (e.g. IgG, IgM, IgA). ELISA may also be adapted to detect PCR products, using immobilised oligonucleotide hybridisation probes and various detection systems.

Immunoblot (Western blot)

Microbial proteins are separated according to molecular weight by polyacrylamide gel electrophoresis (PAGE) and transferred (blotted) on to a nitrocellulose membrane, which is incubated with patient serum. Binding of specific antibody is detected with an enzyme-anti-immunoglobulin conjugate similar to that used in ELISA, and specificity is confirmed by its location on the membrane. Immunoblotting is a highly specific test, which may be used to confirm the results of less specific tests such as ELISA (e.g. in Lyme disease, p. 255).

Fig. 6.6 An overview of the processing of blood cultures. *In laboratories equipped with MALDI-TOF-MS (p. 106), rapid definitive organism identification may be achieved at stage 6 and/or stage 8.
Agglutination tests

When antigens are present on the surface of particles (e.g. cells, latex particles or microorganisms) and cross-linked with antibodies, visible clumping (or ‘agglutination’) occurs.

- **In direct agglutination**, patient serum is added to a suspension of organisms that express the test antigen.

  - **In indirect (passive) agglutination**, specific antigen is attached to the surface of carrier particles, which agglutinate when incubated with patient samples that contain specific antibodies.

  - **In reverse passive agglutination** (an antigen detection test), the carrier particle is coated with antibody rather than antigen.

Other tests

Immunodiffusion involves antibodies and antigen migrating through gels, with or without the assistance of electrophoresis, and forming insoluble complexes where they meet. The complexes are seen on staining as ‘precipitin bands’. Immunodiffusion is used in the diagnosis of dimorphic fungi (p. 300) and some forms of aspergillosis (p. 596).

Immunochromatography is used to detect antigen. The system consists of a porous test strip (e.g. a nitrocellulose membrane), at one end of which there is target-specific antibody, complexed with coloured microparticles. Further specific antibody is immobilised in a transverse narrow line some distance along the strip. Test material (e.g. blood or urine) is added to the antibody–particle complexes, which then migrate along the strip by capillary action. If these are complexed with antigen, they will be immobilised by the specific antibody and visualised as a transverse line across the strip. If the test is negative, the antibody–particle complexes will bind to a line of immobilised anti-immunoglobulin antibody placed further along the strip, which acts as a negative control. Immunochromatographic tests are rapid and relatively cheap to perform, and are appropriate for point-of-care testing, e.g. in HIV 1 and malaria (p. 276).
Antibody-independent specific immunological tests

The interferon-gamma release assay (IGRA) is being used increasingly to diagnose latent tuberculosis infection (LTBI). The principle behind IGRA is discussed on page 594. IGRA cannot distinguish between latent and active tuberculosis infection and is therefore appropriate for use only in countries where the background incidence of tuberculosis is low.

Antimicrobial susceptibility testing

If growth of microorganisms in culture is inhibited by the addition of an antimicrobial agent, the organism is considered to be susceptible to that antimicrobial. Bacteriostatic agents cause reversible inhibition of growth and bactericidal agents cause cell death; the terms fungistatic/fungicidal are equivalent for antifungal agents, and virustatic/virucidal for antiviral agents. The lowest concentration of antimicrobial agent at which growth is inhibited is the minimum inhibitory concentration (MIC), and the lowest concentration that causes cell death is the minimum bactericidal concentration (MBC). If the MIC is less than or equal to a predetermined breakpoint threshold, the organism is considered susceptible, and if the MIC is greater than the breakpoint, it is resistant.

Breakpoints are determined for each antimicrobial agent from a combination of pharmacokinetic (p. 17) and clinical data. The relationship between in vitro antimicrobial susceptibility and clinical response is complex, as response also depends on immune status, pharmacokinetic variability (p. 17), comorbidities that may influence pharmacokinetics or pharmacodynamics, and antibiotic dosing, as well as MIC/MBC. Thus, although treating a patient according to the results of susceptibility testing increases the likelihood of recovery, it does not guarantee therapeutic success.

Susceptibility testing is often carried out by disc diffusion (Fig. 6.10). Antibiotic-impregnated filter paper discs are placed on agar plates containing bacteria; antibiotic diffuses into the agar, resulting in a concentration gradient centred on the disc. Bacteria are unable to grow where the antibiotic concentration exceeds the MIC, which may therefore be inferred from the size of the zone of inhibition. The MIC is commonly measured in diagnostic laboratories using ‘diffusion strips’.

![Diagram](image_url)

**Fig. 6.9** Antibody (Ab) and antigen (Ag) detection by enzyme-linked immunosorbent assay (ELISA). This can be configured in various ways.

A Patient Ab binds to immobilised specific Ag and is detected by addition of anti-immunoglobulin–enzyme conjugate and chromogenic substrate.

B Patient Ab binds to immobilised Ig subclass-specific Ab and is detected by addition of specific Ag, followed by antibody–enzyme conjugate and chromogenic substrate.

C Patient Ab and antibody–enzyme conjugate bind to immobilised specific Ag. Magnitude of colour change reaction is inversely proportional to concentration of patient Ab.

D Patient Ag binds to immobilised Ab and is detected by addition of antibody–enzyme conjugate and chromogenic substrate. In A, the conjugate Ab is specific for human immunoglobulin. In B–D, it is specific for Ag from the disease-causing organism.

**Fig. 6.10** Antimicrobial susceptibility testing by disc diffusion (panels 1–4) and minimum inhibitory concentration (MIC, panel 5).

1. The test organism is spread over the surface of an agar plate.
2. Antimicrobial-impregnated discs (A–F) are placed on the surface and the plate is incubated (e.g. overnight). After incubation, zones of growth inhibition may be seen. The organism is considered susceptible if the diameter of the zone of inhibition exceeds a pre-determined threshold.
3. In a ‘diffusion strip’ test, the strip is impregnated with antimicrobial at a concentration gradient that decreases steadily from top to bottom. The system is designed so that the MIC value is the point at which the ellipse cuts a scale on the strip (arrow).
Epidemiology of infection

The communicability of infectious disease means that, once a clinician has diagnosed an infectious disease, potential exposure of other patients must also be considered. The patient may require separation from other patients ("isolation"), or an outbreak of disease may need to be investigated in the community (Ch. 5). The approach will be specific to the microorganism involved (Chs 11–13) but the principles are outlined below.

Geographical and temporal patterns of infection

Endemic disease

Endemic disease has a constant presence within a given geographical area or population. The infectious agent may have a reservoir, vector or intermediate host that is geographically restricted, or may itself have restrictive environmental requirements (e.g. temperature range, humidity). The population affected may be geographically isolated or the disease may be limited to unvaccinated populations. Factors that alter geographical restriction include:

- expansion of an animal reservoir (e.g. Lyme disease from reforestation)
- vector escape (e.g. airport malaria)
- extension of host range (e.g. schistosomiasis from dam construction)
- human migration (e.g. carbapenemase-producing Klebsiella pneumoniae)
- public health service breakdown (e.g. diphtheria in unvaccinated areas)
- climate change (e.g. dengue virus and Rift Valley fever).

Emerging and re-emerging disease

An emerging infectious disease is one that has newly appeared in a population, or has been known for some time but is increasing in incidence or geographical range. If the disease was previously known and thought to have been controlled or eradicated, it is considered to be re-emerging. Many emerging diseases are caused by organisms that infect animals and have undergone adaptations that enable them to infect humans. This is exemplified by HIV-1, which is believed to have originated in higher primates in Africa. The geographical pattern of some recent emerging and re-emerging infections is shown in Figure 6.11.

Reservoirs of infection

The US Centers for Disease Control (CDC) define a reservoir of infection as any person, other living organism, environment or combination of these in which the infectious agent lives and replicates and on which the infectious agent is dependent for its survival. The infectious agent is transmitted from this reservoir to a susceptible host.

Human reservoirs

Both colonised individuals and those with infection can act as reservoirs, e.g. with Staph. aureus (including MRSA), Strep. pyogenes and C. difficile. For infected humans to act as reservoirs, the infections caused must be long-lasting in at least a proportion of those affected, to enable onward transmission (e.g. tuberculosis, sexually transmitted infections). Humans are the only reservoir for some infections (e.g. measles).

Animal reservoirs

The World Health Organization (WHO) defines a zoonosis as "a disease or infection that is naturally transmissible from vertebrate animals to humans". Infected animals may be asymptomatic. Zoonotic agents may be transmitted via any of the routes described below. Primary infection with zoonoses may be transmitted onward between humans, causing secondary disease (e.g. Q fever, brucellosis, Ebola).

Environmental reservoirs

Many infective pathogens are acquired from an environmental source. However, some of these are maintained in human or animal reservoirs, with the environment acting only as a conduit for infection.
## Transmission of infection

Communicable diseases may be transmitted by one or more of the following routes:

- **Respiratory route**: inhalation.
- **Faecal-oral route**: ingestion of material originating from faeces.
- **Sexually transmitted infections**: direct contact between mucous membranes.
- **Blood-borne infections**: direct inoculation of blood or body fluids.
- **Direct contact**: very few organisms are capable of causing infection by direct contact with intact skin. Most infection by this route requires contact with damaged skin (e.g., surgical wound).
- **Via a vector or fomite**: the vector/fomite bridges the gap between the infected host or reservoir and the uninfected host. Vectors are animate, and include mosquitoes in malaria, dengue and Zika virus infection, fleas in plague and humans in MRSA. Fomites are inanimate objects such as door handles, water taps and ultrasound probes, which are particularly associated with health care-associated infection (HCAI).

The likelihood of infection following transmission of a pathogen depends on organism factors (virulence, p. 104) and host susceptibility. The incubation period is the time between exposure and development of symptoms, and the period of infectivity is the period after exposure during which the patient is infectious to others. Knowledge of incubation periods and of periods of infectivity is important in controlling the spread of disease, although for many diseases these estimates are imprecise (Boxes 6.6 and 6.7).

### 6.6 Incubation periods of important infections

<table>
<thead>
<tr>
<th>Disease</th>
<th>Incubation period</th>

**Intermediate incubation periods**

- Amoebiasis: 1–4 weeks
- Brucellosis: 5–30 days
- Chickenpox: 11–20 days
- Lassa fever: 3–21 days
- Malaria: 10–15 days
- Measles: 6–19 days
- Mumps: 15–24 days
- Poliomyelitis: 3–35 days
- Psittacosis: 1–4 weeks
- Rubella: 15–20 days
- Typhoid: 5–31 days
- Whooping cough: 5–21 days

**Long incubation periods**

- Hepatitis A: 3–7 weeks
- Hepatitis B: 6 weeks to 6 months
- Leishmaniasis, cutaneous: Weeks to months
- Leishmaniasis, visceral: Months to years
- Leprosy (Hansen’s disease): 5–20 years
- Rabies: 2–8 weeks
- Trypanosoma brucei gambiense infection: Months to years
- Tuberculosis: 1–12 months

1Incubation periods are approximate and may differ from local or national guidance. 2Longer incubation periods have been reported. 3WHO. 4Health Protection Agency (now Health Protection England). 5Richardson M, Elliman D, Maguire H, et al. Pediatr Infect Dis J 2001; 20:380–388. 6Centers for Disease Control, USA; cdc.gov/measles/hcp/. 7Bennett JE, Dolin R, Blaser MJ. Mandell, Douglas and Bennett’s Principles and practice of infectious diseases, 8th edn. Philadelphia: Elsevier; 2015. 8Exclude from contact with non-immune and immunocompromised people for 5 days from onset of rash, 9onset of parotitis, or 10start of antibiotic treatment. 9Exclude for 3 weeks if untreated. Durations are approximate and vary between information sources, and these recommendations may differ from local or national guidance.

## Deliberate release

Deliberate release of pathogens with the intention of causing disease is known as biological warfare or bioterrorism, depending on the scale and context. Deliberate release incidents have included a 750-person outbreak of *Salmonella typhimurium* caused by contamination of salads in 1984 (Oregon, USA) and 22 cases of anthrax (five fatal) from the mailing of finely powdered (weaponised) anthrax spores in 2001 (New Jersey, USA). Diseases with high potential for deliberate release include anthrax, plague, tularemia, smallpox and botulism (through toxin release).

### Infection prevention and control

Infection prevention and control (IPC) describes the measures applied to populations with the aim of breaking the chain of infection (see Fig. 6.1, p. 100).

### Health care-associated infection

The risk of developing infection following admission to a health-care facility (health care-associated infection, HCAI)
Commonly encountered health care-associated infections (HCAIs) and the factors that predispose to them.

**Temporary central venous catheter infection**
- Coagulase-negative staphylococci
- *Staphylococcus aureus* (incl. MRSA)
- *Coliforms*
- *Candida*

**Cuffed/tunnelled central venous catheter infection**
- Coagulase-negative staphylococci
- *Staphylococcus aureus* (incl. MRSA)
- *Coliforms*
- *Candida*
- *Pseudomonas* spp.
- *Enterococcus* spp.

**Surgical site infection**

(CPE = carbapenemase-producing Enterobacteriaceae; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staphylococcus aureus*)

---

The developed world is about 10%. Many nosocomial bacterial infections are caused by organisms that are resistant to numerous antibiotics (multi-resistant bacteria), including MRSA, extended-spectrum β-lactamases (ESBLs) and carbapenemase-producing Enterobacteriaceae (CPE), and glycopeptide-resistant enterococci (GRE). Other infections of particular concern in hospitals include *C. difficile* (p. 264) and norovirus (p. 249). Some examples are shown in Figure 6.12.

IPC measures are described in Box 6.8. The most important is maintenance of good hand hygiene (Fig. 6.13). Hand
Wash hands only when visibly soiled! Otherwise use handrub! Duration of the entire procedure: 40–60 sec.

**Fig. 6.13 Hand-washing.** Good hand hygiene, whether with soap/water or alcohol handrub, includes areas that are often missed, such as fingertips, web spaces, palmar creases and the backs of hands. Adapted from the ‘How to Handwash’ URL: who.int/gpsc/5may/How_To_Handwash_Poster.pdf © World Health Organization 2009. All rights reserved.

### 6.9 Types of isolation precaution

<table>
<thead>
<tr>
<th>Airborne transmission</th>
<th>Contact transmission</th>
<th>Droplet transmission</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Precautions</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Negative pressure room with air exhausted externally or filtered</td>
<td>Private room preferred (otherwise, inter-patient spacing ≥ 1 m)</td>
<td>Private room preferred (otherwise, inter-patient spacing ≥ 1 m)</td>
</tr>
<tr>
<td>N95 masks or personal respirators for staff; avoid using non-immune staff</td>
<td>Gloves and gown for staff in contact with patient or contaminated areas</td>
<td>Surgical masks for staff in close contact with patient</td>
</tr>
</tbody>
</table>

**Infections managed with these precautions**

- **Measles**
- Tuberculosis, pulmonary or laryngeal, confirmed or suspected

- Enteroviral infections in young children (diapered or incontinent)
- Norovirus
- C. difficile infection
- Multidrug-resistant organisms (e.g. MRSA, ESBL, GRE, VRSA, penicillin-resistant *S. pneumoniae*)
- Parainfluenza in infants and young children
- Rotavirus
- RSV in infants, children and immunocompromised
- Viral conjunctivitis, acute

**Infections managed with multiple precautions**

- Smallpox, monkeypox, VZV (chickenpox or disseminated disease)
- Adenovirus pneumonia
- SARS, viral haemorrhagic fever

Recommendations based on 2007 CDC guideline for isolation precautions. May differ from local or national recommendations. Not a CDC recommendation. Subject to local risk assessment. Or in any immunocompromised patient until possibility of disseminated infection excluded. (ESBL = extended-spectrum β-lactamase; GRE = glycopeptide-resistant enterococci; MRSA = meticillin-resistant *Staph. aureus*; RSV = respiratory syncytial virus; SARS = severe acute respiratory syndrome; VRSA = vancomycin-resistant *Staph. aureus*; VZV = varicella zoster virus)

Decontamination (e.g. using alcohol gel or washing) is mandatory before and after every patient contact. Decontamination with alcohol gel is usually adequate but hand-washing (with hot water, liquid soap and complete drying) is required after any procedure that involves more than casual physical contact, or if hands are visibly soiled. In situations where the prevalence of *C. difficile* is high (e.g. a local outbreak), alcohol gel decontamination between patient contacts is inadequate as it does not kill *C. difficile* spores, and hands must be washed. Some infections necessitate additional measures to prevent cross-infection (Box 6.9). To minimise risk of infection, invasive procedures must be performed using strict aseptic technique.
Outbreaks of infection

Descriptive terms are defined in Box 6.10. Confirmation of an infectious disease outbreak usually requires evidence from ‘typing’ that the causal organisms have identical phenotypic and/or genotypic characteristics. If this is found not to be the case, the term pseudo-outbreak is used. When an outbreak of infection is suspected, a case definition is agreed. The number of cases that meet the case definition is then assessed by case-finding, using methods ranging from administration of questionnaires to national reporting systems. Case-finding usually includes microbiological testing, at least in the early stages of an outbreak. Temporal changes in cases are noted in order to plot an outbreak curve, and demographic details are collected to identify possible sources of infection. A case–control study, in which recent activities (potential exposures) of affected ‘cases’ are compared to those of unaffected ‘controls’, may be undertaken to establish the outbreak source, and measures are taken to manage the outbreak and control its spread. Good communication between relevant personnel during and after the outbreak is important to inform practice in future outbreaks.

Surveillance ensures that disease outbreaks are either prevented or identified early. In hospitals, staff are made aware of the isolation of alert organisms, which have the propensity to cause outbreaks, and alert conditions, which are likely to be caused by such organisms. Analogous systems are used nationally; many countries publish lists of organisms and diseases, which, if detected (or suspected), must be reported to public health authorities (reportable or notifiable diseases). Reasons for the isolation of alert organisms, which have the propensity to cause outbreaks, and alert conditions, which are likely to be caused by such organisms. Analogous systems are used nationally; many countries publish lists of organisms and diseases, which, if detected (or suspected), must be reported to public health authorities (reportable or notifiable diseases). Reasons for a disease to be classified as reportable are shown in Box 6.11.

### 6.11 Reasons for including an infectious disease on a regional/national list of reportable diseases

<table>
<thead>
<tr>
<th>Reason for inclusion</th>
<th>Examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>Endemic/local disease with the potential to spread and/or cause outbreaks</td>
<td>Influenza, Salmonella, tuberculosis</td>
</tr>
<tr>
<td>Imported disease with the propensity to spread and/or cause outbreaks</td>
<td>Typhoid, cholera (depending on local epidemiology)</td>
</tr>
<tr>
<td>Evidence of a possible breakdown in health protection/public health functions</td>
<td>Legionella, Cryptosporidium</td>
</tr>
<tr>
<td>Evidence of a possible breakdown in food safety practices</td>
<td>Botulism, verotoxigenic E. coli</td>
</tr>
<tr>
<td>Evidence of a possible failure of a vaccination programme</td>
<td>Measles, poliomyelitis, pertussis</td>
</tr>
<tr>
<td>Disease with the potential to be a novel or increasing threat to human health</td>
<td>SARS, MERS-CoV, multi-resistant bacteria</td>
</tr>
<tr>
<td>Evidence of expansion of the range of a reservoir/vector</td>
<td>Lyme disease, rabies, West Nile encephalitis</td>
</tr>
<tr>
<td>Evidence of possible deliberate release</td>
<td>Anthrax, tularemia, plague, smallpox, botulism</td>
</tr>
</tbody>
</table>

*Given the different geographical ranges of individual diseases and wide national variations in public health services, vaccination programmes and availability of resources, reporting regulations vary between regions, states and countries. Many diseases are reportable for more than one reason. (MERS-CoV = Middle East respiratory syndrome coronavirus; SARS = severe acute respiratory syndrome)

### Immunisation

Immunisation may be passive or active. Passive immunisation is achieved by administering antibodies targeting a specific pathogen. Antibodies are obtained from blood, so confer some of the risks associated with blood products (p. 933). The protection afforded by passive immunisation is immediate but of short duration (a few weeks or months); it is used to prevent or attenuate infection before or after exposure (Box 6.12).

### Vaccination

Active immunisation is achieved by vaccination with whole organisms or organism components (Box 6.13).

### Types of vaccine

Whole-cell vaccines consist of live or inactivated (killed) microorganisms. Component vaccines contain only extracted or synthesised components of microorganisms (e.g. polysaccharides or proteins). Live vaccines contain organisms with attenuated (reduced) virulence, which cause only mild symptoms but induce T-lymphocyte and humoral responses (p. 68) and are therefore more immunogenic than inactivated whole-cell vaccines. The use of live vaccines in immunocompromised individuals is not generally recommended, but they may be used by specialists following a risk/benefit assessment.

Component vaccines consisting only of polysaccharides, such as the pneumococcal polysaccharide vaccine (PPV), are poor activators of T lymphocytes and produce a short-lived antibody response without long-lasting memory. Conjugation of polysaccharide to a protein, as in the Haemophilus influenzae type B (Hib) vaccine and the protein conjugate pneumococcal...
Antimicrobial stewardship

Antimicrobial stewardship (AMS) refers to the systems and processes applied to a population to optimise the use of antimicrobial agents. The populations referred to here may be a nation, region, hospital, or a unit within a health-care organisation (e.g. ward or clinic). AMS aims to improve patient outcomes and reduce antimicrobial resistance (AMR). IPC and AMS complement each other (Fig. 6.14). Elements of AMS include treatment guidelines, antimicrobial formularies and ward rounds by infection specialists.

Effective antimicrobial stewardship reduces health care-associated infections
Effective infection control reduces the need for antimicrobials

Fig. 6.14 The relationship between infection prevention and control (IPC) and antimicrobial stewardship (AMS).

6.12 Indications for post-exposure prophylaxis with immunoglobulins

Human normal immunoglobulin (pooled immunoglobulin)
- Hepatitis A (unvaccinated contacts*)
- Measles (exposed child with heart or lung disease)

Human specific immunoglobulin
- Hepatitis B (sexual partners, inoculation injuries, infants born to infected mothers)
- Tetanus (high-risk wounds or incomplete or unknown immunisation status)
- Rabies
- Chickenpox (immuno suppressed children and adults, pregnant women)

*Active immunisation is preferred if contact is with a patient who is within 1 week of onset of jaundice.

6.13 Vaccines in current clinical use

Live attenuated vaccines
- Measles, mumps, rubella (MMR)
- Oral poliovirus (OPV, not used in UK)
- Rotavirus
- Tuberculosis (bacille Calmette–Guérin, BCG)
- Typhoid (oral typhoid vaccine)
- Varicella zoster virus

Inactivated (killed) whole-cell vaccines
- Cholera
- Hepatitis A
- Influenza
- Poliovirus (inactivated polio virus, IPV)
- Rabies

Component vaccines
- Anthrax (adsorbed extracted antigens)
- Diphtheria (adsorbed toxoid)
- Hepatitis B (adsorbed recombinant hepatitis B surface antigen, HBsAg)
- Haemophilus influenzae type B (conjugated capsular polysaccharide)
- Human papillomavirus (recombiant capsid proteins)
- Meningococcal, quadrivalent A, C, Y, W135 (conjugated capsular polysaccharide)
- Meningococcal, serogroup C (conjugated capsular polysaccharide)
- Pertussis (adsorbed extracted antigens)
- Pneumococcal conjugate (PCV; conjugated capsular polysaccharide, 13 serotypes)
- Pneumococcal polysaccharide (PPV; purified capsular polysaccharide, 23 serotypes)
- Tetanus (adsorbed toxoid)
- Typhoid (purified Vi capsular polysaccharide)

Vaccine (PCV), activates T lymphocytes, which results in a sustained response and immunological memory. Toxoids are bacterial toxins that have been modified to reduce toxicity but maintain antigenicity. Vaccine response can be improved by co-administration with mildly pro-inflammatory adjuvants, such as aluminium hydroxide.

Use of vaccines

Vaccination may be applied to entire populations or to subpopulations at specific risk through travel, occupation or other activities. In ring vaccination, the population immediately surrounding a case or outbreak of infectious disease is vaccinated to curtail further spread. Vaccination is aimed mainly at preventing infectious disease. However, vaccination against human papillomavirus (HPV) was introduced to prevent cervical and other cancers that complicate HPV infection. Vaccination guidelines for individuals are shown in Box 6.14.

Vaccination becomes successful once the number of susceptible hosts in a population falls below the level required to sustain continued transmission of the target organism (herd immunity). Naturally acquired smallpox was declared to have been eradicated worldwide in 1980 through mass vaccination. In 1988, the WHO resolved to eradicate poliomyelitis by vaccination; the number of cases worldwide has since fallen from approximately 350,000 per annum to 74 in 2015. Recommended vaccination schedules vary between countries. In addition to standard vaccination schedules, catch-up schedules are specified for individuals who join vaccination programmes later than the recommended age.

6.14 Guidelines for vaccination against infectious disease

- The principal contraindication to inactivated vaccines is an anaphylactic reaction to a previous dose or a vaccine component
- Live vaccines should not be given during an acute infection, to pregnant women or to the immunosuppressed, unless the immunosuppression is mild and the benefits outweigh the risks
- If two live vaccines are required, they should be given either simultaneously in opposite arms or 4 weeks apart
- Live vaccines should not be given for 3 months after an injection of human normal immunoglobulin (HNI)
- HNI should not be given for 2 weeks after a live vaccine
- Hay fever, asthma, eczema, sickle-cell disease, topical glucocorticoid therapy, antibiotic therapy, prematurity and chronic heart and lung diseases, including tuberculosis, are not contraindications to vaccination
Treatment of infectious diseases

Key components of treating infection are:
- optimising antimicrobial therapy while minimising selection for antimicrobial resistance and the impact on commensal flora
- addressing predisposing factors, e.g. glycaemic control in diabetes mellitus; viral load control in HIV-1-associated opportunistic infection
- considering adjuvant therapy, e.g. removal of an infected medical device or necrotic tissue
- managing complications, e.g. severe sepsis (systemic inflammatory response syndrome, or SIRS, p. 196) and acute kidney injury (p. 411).

For communicable disease, treatment must also take into account contacts of the infected patient, and may include IPC interventions such as isolation, antimicrobial prophylaxis, vaccination and contact tracing.

Principles of antimicrobial therapy

In some situations (e.g. pneumonia) it is important to start appropriate antimicrobial therapy promptly, whereas in others prior confirmation of the diagnosis and pathogen is preferred. The principles underlying the choice of antimicrobial agent(s) are discussed below. The WHO ‘World Antibiotic Awareness Week’ campaign is a yearly event aimed at highlighting the importance of prudent antimicrobial prescribing (see ‘Further information’).

Antimicrobial action and spectrum

Antimicrobial agents may kill or inhibit microorganisms by targeting essential and non-essential cellular processes, respectively. The range, or spectrum, of microorganisms that is killed or inhibited by a particular antimicrobial agent needs consideration when selecting therapy. Mechanisms of action of the major classes of antibacterial agent are listed in Box 6.15 and appropriate agents for some common infecting organisms are shown in Box 6.16. In severe infections and/or immunocompromised patients, it is customary to use bactericidal agents in preference to bacteriostatic agents.

Empiric versus targeted therapy

Empiric antimicrobial therapy is selected to treat a suspected infection (e.g. meningitis) before the microbiological cause is known. Targeted or ‘directed’ therapy can be prescribed when the pathogen(s) is known. Empirical antimicrobial regimens need to have activity against the range of pathogens that could be causing the infection in question; because broad-spectrum agents affect many more bacteria than needed, they select for antimicrobial resistance. ‘Start Smart – Then Focus’ (Fig. 6.15) describes the principle of converting from empiric therapy to narrow-spectrum targeted therapy. Optimum empiric therapy depends on the site of infection, patient characteristics and local antimicrobial resistance patterns. National or local guidelines are often used to inform antimicrobial prescribing decisions.

Combination therapy

It is sometimes appropriate to combine antimicrobial agents:
- when there is a need to increase clinical effectiveness (e.g. biofilm infections)
- when no single agent’s spectrum covers all potential pathogens (e.g. polymicrobial infection)
- when there is a need to reduce development of antimicrobial resistance in the target pathogen, as the organism would need to develop resistance to multiple agents simultaneously (e.g. antituberculous chemotherapy, p. 592; antiretroviral therapy (ART), p. 324).

Antimicrobial resistance

Microorganisms have evolved in the presence of naturally occurring antibiotics and have therefore developed resistance mechanisms (categorised in Fig. 6.16) to all classes of antimicrobial agent (antibiotics and their derivatives). Intrinsic resistance is an innate property of a microorganism, whereas acquired resistance arises by spontaneous mutation or horizontal transfer of genetic material from another organism (e.g. via a plasmid, p. 100). Plasmids often encode resistance to multiple antibiotics.

The mecA gene encodes a penicillin-binding protein, which has a low affinity for penicillins and therefore confers resistance to β-lactam antibiotics in staphylococci. Extended-spectrum β-lactamases (ESBLs) are frequently encoded on plasmids, which are transferred relatively easily between bacteria, including Enterobacteriaceae. Plasmid-encoded carbapenemases have been detected in strains of *Klebsiella pneumoniae* (e.g. New Delhi metallo-β-lactamase 1, NDM-1). Strains of MRSA have been described that also have reduced susceptibility to glycopeptides through the development of a relatively impermeable cell wall.

*Antibiotic selection depends on multiple factors, including local susceptibility patterns, which vary enormously between geographical areas. There are many appropriate alternatives to those listed. (ESBL = extended-spectrum β-lactamase; MRSA = meticillin-resistant *Staphylococcus aureus*).

Pharmacokinetics and pharmacodynamics

Pharmacokinetics of antimicrobial agents determine whether adequate concentrations are obtained at the sites of infection. Septic patients often have poor gastrointestinal absorption, so the preferred initial route of therapy is intravenous. Knowledge of anticipated antimicrobial drug concentrations at sites of infection is critical. For example, achieving a ‘therapeutic’ blood level of gentamicin is of little practical use in treating meningitis, as CSF penetration of the drug is poor. Knowledge of routes of antimicrobial elimination is also critical; for instance, urinary tract infection is ideally treated with a drug that is excreted unchanged in the urine.

Pharmacodynamics describes the relationship between antimicrobial concentration and microbial killing. For many agents, antimicrobial effect can be categorised as ‘concentration-dependent’ or ‘time-dependent’. The concentration of antimicrobial achieved after a single dose is illustrated in Figure 6.17. The maximum concentration achieved is $C_{\text{max}}$ and the measure of overall exposure is the area under the curve (AUC). The efficacy of antimicrobial agents whose killing is concentration-dependent (e.g. aminoglycosides) increases with the amount by which $C_{\text{max}}$ exceeds the minimum inhibitory concentration ($C_{\text{max}} : \text{MIC}$ ratio). For this reason, it has become customary to administer aminoglycosides (e.g. gentamicin) infrequently at high doses (e.g. 7 mg/kg) rather than frequently at low doses. This has the added advantage of minimising toxicity by reducing the likelihood of antimicrobial resistance.

Duration of therapy

Treatment duration reflects the severity of infection and accessibility of the infected site to antimicrobial agents. For most infections, there is limited evidence available to support a specific duration of treatment (Box 6.17). Depending on the indication, initial intravenous therapy can often be switched to oral as soon as the patient is afebrile and improving. In the absence of specific guidance, antimicrobial therapy should be stopped when there is no longer any clinical evidence of infection.
different for each class of agent). This is reflected in the dosing killing), time above MIC (time-dependent killing) and AUC : MIC ratio.

and often less well understood. With some agents, bacterial agents, the pharmacodynamic relationships are more complex be administered by continuous infusion. For other antimicrobial in severe infection (e.g. meningococcal meningitis), and may interval of benzylpenicillin, which is usually given every 4 hours of drug accumulation. Conversely, the β-lactam antibiotics and vancomycin exhibit time-dependent killing, and their efficacy depends on $C_{\text{max}}$ exceeding the MIC for a certain time (which is different for each class of agent). This is reflected in the dosing interval of benzylpenicillin, which is usually given every 4 hours in severe infection (e.g. meningococcal meningitis), and may be administered by continuous infusion. For other antimicrobial agents, the pharmacodynamic relationships are more complex and often less well understood. With some agents, bacterial inhibition persists after antimicrobial exposure (post-antibiotic and post-antibiotic sub-MIC effects).

### Therapeutic drug monitoring

Therapeutic drug monitoring is used to confirm that levels of antimicrobial agents with a low therapeutic index (e.g. aminoglycosides) are not excessive, and that levels of agents with marked pharmacokinetic variability (e.g. vancomycin) are adequate. Specific recommendations for monitoring depend on individual clinical circumstances; for instance, different pre- and post-dose levels of gentamicin are recommended, depending on whether it is being used in traditional divided doses, once daily or for synergy in endocarditis (p. 530).

### Antimicrobial prophylaxis

Antimicrobial prophylaxis is the use of antimicrobial agents to prevent infection. Primary prophylaxis is used to reduce the risk of infection following certain medical procedures (e.g. colonic resection or prosthetic hip insertion), following exposure to a specific pathogen (e.g. Bordetella pertussis) or in specific situations such as post-splenectomy (Box 6.18). It should be

- Influenza A (prevention of secondary cases in adults with chronic respiratory, cardiovascular or renal disease, immunosuppression or diabetes mellitus)

**Fungal**

- Aspergillosis (in high-risk haematology patients)
- Pneumocystis pneumonia (prevention in HIV and other immunosuppressed states)

**Protozoal**

- Malaria (prevention of travel-associated disease)

*These are based on current UK practice. Recommendations may vary locally or nationally. Antimicrobial prophylaxis for infective endocarditis during dental procedures is not currently recommended in the UK.
associated with minimal adverse effects. In the case of exposure, it may be combined with passive immunisation (see Box 6.12). Secondary prophylaxis is used in patients who have been treated successfully for an infection but remain predisposed to it. It is used in haemato-oncology patients in the context of fungal infection and in HIV-positive individuals with an opportunistic infection until a defined level of immune reconstitution is achieved.

Antibacterial agents

For details of antibacterial usage in pregnancy and old age, see Boxes 6.19 and 6.20.

### 6.20 Problems with antimicrobial therapy in old age

- **Clostridium difficile infection**: all antibiotics predispose to some extent, but second- and third-generation cephalosporins, co-amoxiclav and fluoroquinolones (e.g. ciprofloxacin) especially so.
- **Hypersensitivity reactions**: rise in incidence due to increased previous exposure.
- **Renal impairment**: may be significant in old age, despite ‘normal’ creatinine levels (p. 386).
- **Nephrotoxicity**: more likely, e.g. first-generation cephalosporins, aminoglycosides.
- **Accumulation of β-lactam antibiotics**: may result in myoclonus, seizures or coma.
- **Reduced gastric acid production**: gastric pH is higher, which causes increased penicillin absorption.
- **Reduced hepatic metabolism**: results in a higher risk of isoniazid-related hepatotoxicity.
- **Quinolones**: associated with delirium and may increase the risk of seizures.

### Beta-lactam antibiotics

These antibiotics have a β-lactam ring structure and exert a bactericidal action by inhibiting enzymes involved in cell wall synthesis (penicillin-binding proteins, PBPs). They are classified in Box 6.21.

#### Pharmacokinetics

- Good drug levels are achieved in lung, kidney, bone, muscle and liver, and in pleural, synovial, pericardial and peritoneal fluids.
- CSF levels are low, except when meninges are inflamed.
- Activity is not inhibited in abscess (e.g. by low pH and PO2, high protein or neutrophils).
- Beta-lactams are subject to an ‘inoculum effect’ – activity is reduced in the presence of a high organism burden (PBP expression is down-regulated by high organism density).
- Generally safe in pregnancy (except imipenem/cilastatin).

#### Adverse effects

Immediate (IgE-mediated) allergic reactions are rare but life-threatening. Approximately 90% of patients who report a penicillin allergy do not have a true IgE-mediated allergy. Other reactions, such as rashes, fever and haematological effects (e.g. low white cell count), usually follow more prolonged therapy (more than 2 weeks). A large proportion of patients with infectious mononucleosis develop a rash if given aminopenicillins; this does not imply lasting allergy. The relationship between allergy to penicillin and allergy to cephapslorins depends on the specific cephalosporin used; there is significant cross-reactivity with first-generation cephalosporins but cross-reactivity to second- or third-generation cephalosporins is less common. Avoidance of cephalosporins, however, is recommended in patients who have IgE-mediated penicillin allergy (p. 84). Cross-reactivity between penicillin and carbapenems is rare (approximately 1% by skin testing) and carbapenems may be administered if there are no suitable alternatives and appropriate resuscitation facilities are available. The monobactam aztreonam (p. 121) is the β-lactam least likely to cross-react in patients with penicillin allergy.

Gastrointestinal upset and diarrhoea are common, and a mild reversible hepatitis is recognised with many β-lactams. More severe forms of hepatitis can be observed with fluclxacillin and co-amoxiclav. Leucopenia, thrombocytopenia, coagulation...
deficiencies, interstitial nephritis and potentiation of aminoglycoside-mediated kidney damage are also recognised (p. 122). Seizures and encephalopathy have been reported, particularly with high doses in the presence of renal insufficiency. Thrombophlebitis occurs in up to 5% of patients receiving parenteral β-lactams.

**Drug interactions**

Synergism occurs in combination with aminoglycosides in vitro. Ampicillin decreases the biological effect of oral contraceptives and the whole class is significantly affected by concurrent administration of probenecid, producing a 2–4-fold increase in the peak serum concentration.

**Penicillins**

Natural penicillins are primarily effective against Gram-positive organisms (except staphylococci, most of which produce a penicillinase) and anaerobic organisms. Strep. pyogenes has remained sensitive to natural penicillins worldwide. According to the European Antimicrobial Resistance Surveillance Network (EARS-Net), the prevalence of non-susceptibility to penicillin in Strep. pneumoniae in Europe in 2014 varied widely from 0% (Cyprus) to 46.7% (Romania).

Penicillinase-resistant penicillins are the mainstay of treatment for infections with Staph. aureus, other than MRSA. However, EARS-Net data from 2014 indicate that MRSA rates in Europe vary widely from 0.9% (Netherlands) to 56% (Romania). Aminopenicillins have the same spectrum of activity as the natural penicillins, with additional Gram-negative cover against Enterobacteriaceae. Amoxicillin has better oral absorption than ampicillin. Unfortunately, resistance to these agents is widespread (57.1% of E. coli Europe-wide in 2014, range 34.7–73%), so they are no longer appropriate for empirical use in Gram-negative infections. In many organisms, resistance is due to β-lactamase production, which can be overcome by the addition of β-lactamase inhibitors (clavulanic acid or sulbactam).

Carboxypenicillins (e.g. ticarcillin) and ureidopenicillins (e.g. piperacillin) are particularly active against Gram-negative organisms, especially Pseudomonas spp., which are resistant to the aminopenicillins. Beta-lactamase inhibitors may be added to extend their spectrum of activity (e.g. piperacillin–tazobactam). Temocillin is derived from ticarcillin; it has good activity against Enterobacteriaceae, including those that produce ESBL enzymes, but poor activity against Pseudomonas aeruginosa and Gram-positive bacteria.

**Cephalosporins and cephamycins**

Cephalosporins are broad-spectrum agents. Unfortunately, their use is associated with CDI (p. 264). With the exception of cefotiboprole, the group has no activity against enterococci. Only the cephamycins have anti-anaerobic activity. All cephalosporins are inactivated by ESBL. Cephalosporins are arranged in ‘generations’ (Box 6.22).

- **First-generation compounds** have excellent activity against Gram-positive organisms and some activity against Gram-negatives.
- **Second-generation drugs** retain Gram-positive activity but have extended Gram-negative activity. Cephamycins (e.g. cefoxitin), included in this group, are active against anaerobic Gram-negative bacilli.
- **Third-generation agents** further improve anti-Gram-negative cover. For some (e.g. ceftriaxime), this is extended to include Pseudomonas spp. Cefotaxime and ceftriaxone have excellent Gram-negative activity and retain good activity against Strep. pneumoniae and β-haemolytic streptococci. Ceftriaxone is administered once daily and is therefore a suitable agent for outpatient intravenous (parenteral) antimicrobial therapy (OPAT).
- **Fourth-generation agents**, e.g. cefpirome, have a broad spectrum of activity, including streptococci and some Gram-negatives, including P. aeruginosa.
- **Fifth-generation agents**, such as ceftobiprole and ceftaroline, have an enhanced spectrum of Gram-positive activity that includes MRSA, and also have activity against Gram-negative bacteria; some, such as ceftobiprole, are active against P. aeruginosa.

The spectrum of cephalosporins has also been enhanced by adding β-lactamase inhibitors.

**Monobactams**

Aztreonam is the only available monobactam. It is active against Gram-negative bacteria, except ESBL-producing organisms, but inactive against Gram-positive organisms or anaerobes. It is a parenteral-only agent and may be used safely in most penicillin-allergic patients other than those with an allergy to ceftazidime, which shares a common side chain with aztreonam.

**Carbapenems**

These intravenous agents have the broadest antibiotic activity of the β-lactam antibiotics, covering most clinically significant bacteria, including anaerobes (e.g. imipenem, meropenem, ertapenem).

### 6.22 Cephalosporins

<table>

</tr>
</tbody>
</table>
- Frequency of administration: erythromycin is administered 4 times daily, clarithromycin twice daily, azithromycin once daily.
- High protein binding.
- Excellent intracellular accumulation.

**Lincosamides (e.g. clindamycin)**
- Good oral bioavailability.
- Food has no effect on absorption.
- Good bone/joint penetration; limited CSF penetration.

**Adverse effects**
- Gastrointestinal upset, especially in young adults (erythromycin 30%).
- Cholestatic jaundice with erythromycin estolate.
- Prolongation of QT interval can cause torsades de pointes (p. 476).
- Clindamycin predisposes to CDI.

**Aminoglycosides and spectinomycin**
Aminoglycosides are effective mainly in Gram-negative infections and are therefore commonly used in regimens for intra-abdominal infection. Some aminoglycosides, e.g. amikacin, are important components of therapy for MDR-TB. Because they act synergistically with β-lactam antibiotics they are used in combinations to treat biofilm infections, including infective endocarditis and orthopaedic implant infections. They cause very little local irritation at injection sites and negligible allergic responses. Oto- and nephrotoxicity must be avoided by monitoring of renal function and drug levels and by use of short treatment regimens. Aminoglycosides are not subject to an inoculum effect (p. 120) and they all exhibit a post-antibiotic effect (p. 119).

**Pharmacokinetics**
- Negligible oral absorption.
- Hydrophilic, so excellent penetration to extracellular fluid in body cavities and serosal fluids.
- Very poor intracellular penetration (except hair cells in cochlea and renal cortical cells).
- Negligible CSF and corneal penetration and may require intrathecal administration during neurosurgical infections.
- Peak plasma levels 30 minutes after infusion.
- Monitoring of therapeutic levels required.

**Gentamicin dosing**
- Except in certain forms of endocarditis, pregnancy, severe burns, end-stage renal disease and paediatric patients, gentamicin is administered at 7 mg/kg body weight. The appropriate dose interval depends on drug clearance and is determined by reference to the Hartford nomogram (Fig. 6.18).
- In streptococcal and enterococcal endocarditis, gentamicin is used with a cell wall active agent (usually a β-lactam), to provide synergy. Commonly used doses are 1 mg/kg 2–3 times daily for enterococcal endocarditis and 3 mg/kg once daily for most strains of oral streptococci. Target pre- and post-dose levels are <1 mg/L and 3–5 mg/L, respectively, when gentamicin is dosed 3 times daily.
- When not used according to the Hartford regimen or for endocarditis, gentamicin is administered twice or 3 times daily at 3–5 mg/kg/day. Target pre- and post-dose levels are <1 mg/L and 5–10 mg/L (7–10 mg/L with less sensitive organisms, e.g. *P. aeruginosa*), respectively.
- For other aminoglycosides, consult local guidance.

**Spectinomycin**
Chemically similar to the aminoglycosides and given intramuscularly, spectinomycin was developed to treat strains of *Neisseria gonorrhoeae* resistant to β-lactam antibiotics. Unfortunately, resistance to spectinomycin is very common. Its only indication is the treatment of gonococcal urethritis in pregnancy or in patients allergic to β-lactam antibiotics.

**Quinolones and fluoroquinolones**
These are effective and generally well-tolerated bactericidal agents. The quinolones have purely anti-Gram-negative activity, whereas the fluoroquinolones are broad-spectrum agents (Box 6.23). Ciprofloxacin has anti-pseudomonal activity but resistance emerges rapidly. In 2014, European surveillance showed that resistance to fluoroquinolones in *E. coli* ranged between 7.8% (Iceland) and 46.4% (Cyprus). Quinolones and fluoroquinolones are used for a variety of common infections, including urinary tract infection and pneumonia, and less common problems like MDR-TB.

**Pharmacokinetics**
- Well absorbed after oral administration but delayed by food, antacids, ferrous sulphate and multivitamins.
- Wide volume of distribution; tissue concentrations twice those in serum.
- Good intracellular penetration, concentrating in phagocytes.
Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are effective against Gram-positive organisms only, and are used against MRSA and ampicillin-resistant enterococci. Some staphylococci and enterococci demonstrate intermediate sensitivity or resistance. Vancomycin use should be restricted to limit emergence of resistant strains. Teicoplanin is not available in all countries. Neither drug is absorbed after oral administration but vancomycin is used orally to treat CDI.

Pharmacokinetics

**Vancomycin**

- Administered by slow intravenous infusion, good tissue distribution and short half-life.
- Enters the CSF only in the presence of inflammation and may require intrathecal administration during neurosurgical infections.
- Therapeutic monitoring of intravenous vancomycin is recommended, to maintain pre-dose levels of >10 mg/L (15–20 mg/L in serious staphylococcal infections).

**Teicoplanin**

- Long half-life allows once-daily dosing.

### Adverse effects

- Histamine release due to rapid vancomycin infusion produces a ‘red man’ reaction (rare with modern preparations).
- Nephrotoxicity is rare but may occur with concomitant aminoglycoside use, as may ototoxicity.
- Teicoplanin can cause rash, bronchospasm, eosinophilia and anaphylaxis.

### Lipopeptides

Daptomycin is a cyclic lipopeptide with bactericidal activity against Gram-positive organisms (including MRSA and GRE) but not Gram-negatives. It is not absorbed orally, and is used intravenously to treat Gram-positive infections, such as soft tissue infections and Staph. aureus infective endocarditis. Daptomycin is not effective for community-acquired pneumonia. Treatment can be associated with increased levels of creatine kinase and eosinophilic pneumonitis.

### Polymyxins

Colistin is a polymyxin antibiotic that binds and disrupts the outer cell membrane of Gram-negative bacteria, including P. aeruginosa and Acinetobacter baumannii. Its use has increased with the emergence and spread of multi-resistant Gram-negative bacteria, including CPEs. It can be administered by oral, intravenous and nebulised routes. Significant adverse effects include neurotoxicity, including encephalopathy, and nephrotoxicity.

### Folate antagonists

These are bacteriostatic antibacterials (p. 109). A combination of a sulphonamide and either trimethoprim or pyrimethamine is most commonly used, which interferes with two consecutive steps in the metabolic pathway. Available combinations include trimethoprim/sulfamethoxazole (co-trimoxazole) and pyrimethamine with either sulfadoxine (used to treat malaria) or sulfadiazine (used in toxoplasmosis). Co-trimoxazole is the first-line drug for Pneumocystis jiroveci infection, the second-line drug for treatment and prevention of B. pertussis (whooping cough) infection, and is also used for a variety of other infections, including Staph. aureus. Dapsone is used to treat leprosy (Hansen’s disease) and to prevent toxoplasmosis and pneumocystis when patients are intolerant of other medications. Folinic acid should be given to prevent myelosuppression if these drugs are used long-term or unavoidably in early pregnancy.

Pharmacokinetics

- Well absorbed orally.
- Sulphonamides are hydrophilic, distributing well to the extracellular fluid.
- Trimethoprim is lipophilic with high tissue concentrations.

### Adverse effects

- Trimethoprim is generally well tolerated, with few adverse effects.
- Sulphonamides and dapsone may cause haemolysis in glucose-6-phosphate dehydrogenase deficiency (p. 948).
- Sulphonamides and dapsone cause skin and mucocutaneous reactions, including Stevens–Johnson syndrome and ‘dapsone syndrome’ (rash, fever and lymphadenopathy).
- Dapsone causes methaemoglobinaemia (p. 135) and peripheral neuropathy.
Tetracyclines and glycyclcyclines

Tetracyclines

Of this mainly bacteriostatic class, the newer drugs doxycycline and minocycline show better absorption and distribution than older ones. Many streptococci and Gram-negative bacteria are now resistant, in part due to their use in animals (which is banned in Europe). Tetracyclines are indicated for Mycoplasma spp., Chlamydia spp., Rickettsia spp., Coxiella spp., Bartonella spp., Borrelia spp., Helicobacter pylori, Treponema pallidum and atypical mycobacterial infections. Tetracyclines can also be used for malaria prevention.

Pharmacokinetics

• Best oral absorption is in the fasting state (doxycycline is 100% absorbed unless gastric pH rises) and absorption is inhibited by cations, e.g. calcium or iron, which should not be administered at the same time.

Adverse effects

• All tetracyclines except doxycycline are contraindicated in renal failure.
• Dizziness with minocycline.
• Binding to metallic ions in bones and teeth causes discoloration (avoid in children and pregnancy) and enamel hypoplasia.
• Oesophagitis/oesophageal ulcers with doxycycline.
• Phototoxic skin reactions.

Glycyclcyclines (tigecycline)

Chemical modification of tetracycline has produced tigecycline, a broad-spectrum, parenteral-only antibiotic with activity against resistant Gram-positive and Gram-negative pathogens, such as MRSA and ESBL (but excluding Pseudomonas spp.). Re-analysis of trial data has shown that there was excess mortality following tigecycline treatment as opposed to comparator antibiotics, so tigecycline should be used only when there has been adequate assessment of risk versus benefit.

Nitroimidazoles

Nitroimidazoles are highly active against strictly anaerobic bacteria, especially Bacteroides fragilis, C. difficile and other Clostridium spp. They also have significant antiprotozoal activity against amoebae and Giardia lamblia.

Pharmacokinetics

• Almost completely absorbed after oral administration (60% after rectal administration).
• Well distributed, especially to brain and CSF.
• Safe in pregnancy.

Adverse effects

• Metallic taste (dose-dependent).
• Severe vomiting if taken with alcohol – ‘Antabuse effect’.
• Peripheral neuropathy with prolonged use.

Phenicols

Chloramphenicol is the only example in clinical use. In developed countries its use tends to be reserved for severe and life-threatening infections when other antibiotics are either unavailable or impractical, largely because of concerns about toxicity. It is bacteriostatic to most organisms but apparently bactericidal to H. influenzae, Strep. pneumoniae and N. meningitidis. It has a very broad spectrum of activity against aerobic and anaerobic organisms, spirochaetes, Rickettsia, Chlamydia and Mycoplasma spp. It competes with macrolides and lincosamides for ribosomal binding sites, so should not be used in combination with these agents. Significant adverse effects are ‘grey baby’ syndrome in infants (cyanosis and circulatory collapse due to inability to conjugate drug and excrete the active form in urine); reversible dose-dependent bone marrow depression in adults receiving high cumulative doses; and severe aplastic anaemia in 1 in 25 000–40 000 exposures (unrelated to dose, duration of therapy or route of administration).

Oxazolidinones

Linezolid and tedizolid are examples and their good activity against Gram-positive organisms means they are often used to treat skin and soft tissue infections. They may also be used in infection caused by resistant Gram-positive bacteria, including MRSA and GRE. Administration can be intravenous or oral. Common linezolid adverse effects include mild gastrointestinal upset and tongue discoloration. Myelodysplasia and peripheral and optic neuropathy can occur with prolonged use. Linezolid has monoamine oxidase inhibitor (MAOI) activity, and co-administration with other MAOIs or serotonin re-uptake inhibitors should be avoided, as this may precipitate a ‘serotonin syndrome’ (p. 1199).

Other antibacterial agents

Fusidic acid

This antibiotic, active against Gram-positive bacteria, is available in intravenous, oral or topical formulations. It is lipid-soluble and distributes well to tissues. Its antibacterial activity is, however, unpredictable. Fusidic acid is used in combination, typically with antistaphylococcal penicillins, or for MRSA with clindamycin or rifampicin. It interacts with coumarin derivatives and oral contraceptives.

Nitrofurantoin

This drug has very rapid renal elimination and is active against aerobic Gram-negative and Gram-positive bacteria, including enterococci. It is used only for treatment of urinary tract infection, being generally safe in pregnancy and childhood. With prolonged treatment, however, it can cause eosinophilic lung infiltrates, fever, pulmonary fibrosis, peripheral neuropathy, hepatitis and haemolytic anaemia so its use must be carefully balanced against risks.

Fidaxomicin

Fidaxomicin is an inhibitor of RNA synthesis, and was introduced for the treatment of CDI in 2012. In non-severe CDI it is non-inferior to oral vancomycin and is associated with a lower recurrence rate. Its effectiveness has not been assessed in severe CDI.

Fosfomycin

Fosfomycin acts by inhibiting cell wall synthesis. It has activity against Gram-negative but also Gram-positive bacteria and can demonstrate in vitro synergy against MRSA when combined with other antimicrobials. It is used for treatment of urinary tract infections but can be employed in other situations against multi-resistant bacteria.
Antimycobacterial agents

**Isoniazid**
Isoniazid is bactericidal for replicating bacteria and bacteriostatic for non-replicating bacteria. It is activated by mycobacterial catalase-peroxidase (KatG) and inhibits the InhA gene product, a reductase involved in mycolic acid synthesis. Mutations in KatG or InhA result in isoniazid resistance, which was reported in 15% of cases of *M. tuberculosis* infection globally in 2013. Isoniazid is well absorbed orally and metabolised by acetylation in the liver. The major side-effects are hepatitis, neuropathy (ameliorated by co-administration of pyridoxine) and hypersensitivity reactions.

**Rifampicin**
Rifampicin inhibits DNA-dependent RNA polymerase and is bactericidal against replicating bacteria. It is also active in necrotic foci, where mycobacteria have low levels of replication, and is therefore important in sterilisation and sputum conversion. Resistance most often involves the β-subunit of RNA polymerase and most often occurs with isoniazid-resistant MDR-TB. Rifampicin is well absorbed orally. It is metabolised by the liver via the microsomal cytochrome P450 system and is one of the most potent inducers of multiple P450 isoenzymes, so is subject to extensive drug–drug interactions. Common side-effects include hepatitis, influenza-like symptoms and hypersensitivity reactions. Orange discolouration of urine and body secretions is expected.

**Pyrazinamide**
The mechanism of action of pyrazinamide is incompletely defined but includes inhibition of fatty acid synthase and ribosomal trans-translation. Pyrazinamide is often bacteriostatic but can be bactericidal and is active against semi-dormant bacteria in a low-pH environment. Primary resistance is rare but MDR-TB strains are frequently pyrazinamide-resistant and intrinsic resistance is a feature of *Mycobacterium bovis* strains. Pyrazinamide is well absorbed orally and metabolised by the liver. Side-effects include nausea, hepatitis, asymptomatic elevation of uric acid and myalgia.

**Ethambutol**
Ethambutol is a bacteriostatic agent. It inhibits arabinosyl transferase, which is involved in the synthesis of arabinoalactan, a component of the mycobacterial cell wall. Resistance is usually seen when resistance to other antimycobacterial agents is also present, e.g. in MDR-TB strains. It is orally absorbed but, in contrast to the first-line agents described above, it achieves poor CSF penetration and is renally excreted. The major side-effect is optic neuritis with loss of red–green colour discrimination and impaired visual acuity. It can also cause hepatitis.

**Streptomycin**
Streptomycin is an aminoglycoside whose mechanism of action and side-effects are similar to those of other aminoglycosides. It is administered intramuscularly.

**Other antituberculous agents**
Second-line agents used in MDR or XDR strains (p. 116) include aminoglycosides (amikacin, capreomycin or kanamycin) and fluoroquinolones (moxifloxacin or levofloxacin), discussed above. Other established second-line agents administered orally are cycloserine (which causes neurological side-effects); ethionamide or prothionamide (which are not active with InhA-gene-mediated resistance but have reasonable CSF penetration; their side-effect profile includes gastrointestinal disturbance, hepatotoxicity and neurotoxicity); and paraaminosalicylic acid (which causes rashes and gastrointestinal upset). Linezolid may also be used and has good CSF penetration, while meropenem with co-amoxiclav is occasionally chosen. New drugs developed for XDR-TB include delamanid and bedaquiline; their adverse effects include QT prolongation and cardiac arrhythmias. Their co-administration with other agents with a similar side-effect profile (e.g. fluoroquinolones) therefore requires careful risk assessment.

**Clofazimine**
Clofazimine is used against *M. leprae* and resistant strains of *M. tuberculosis*. Its mode of action may involve induction of oxidative stress and it is weakly bactericidal. Oral absorption is variable and it is excreted in the bile. Side-effects include gastrointestinal upset, dry eyes and skin, and skin pigmentation, especially in those with pigmented skin.

### Antifungal agents

See Box 6.24.

Azole antifungals

The azoles (imidazoles and triazoles) inhibit synthesis of ergosterol, a constituent of the fungal cell membrane. Side-effects vary but include gastrointestinal upset, hepatitis and rash. Azoles are inhibitors of cytochrome P450 enzymes, so tend to increase exposure to cytochrome P450-metabolised drugs (p. 24).

Imidazoles

Miconazole, econazole, clotrimazole and ketoconazole are relatively toxic and therefore administered topically. Clotrimazole is used extensively to treat superficial fungal infections. Triazoles are used for systemic treatment because they are less toxic.

TriaZoles

Flucytosine is effective against yeasts (Candida and Cryptococcus spp.) and has a long half-life (approximately 30 hours) and an excellent safety profile. The drug is highly water-soluble and distributes widely to all body sites and tissues, including CSF. Itraconazole is lipophilic and distributes extensively, including to toenails and fingernails. CSF penetration is poor. Because oral absorption is erratic, therapeutic drug monitoring is required. Voriconazole is well absorbed orally but variability in levels requires therapeutic drug monitoring. It is used mainly in aspergillosis (p. 596). Side-effects include photosensitivity, hepatitis and transient retinal toxicity. Posaconazole and isavuconazole are broad-spectrum azoles, with activity against Candida spp., Aspergillus spp. and some mucoraceous moulds. Isavuconazole is non-inferior to voriconazole in the management of invasive aspergillosis and may be considered as an alternative when voriconazole is not tolerated.

Echinocandins

The echinocandins inhibit β-1,3-glucan synthesis in the fungal cell wall. They have few significant adverse effects. Caspofungin, anidulafungin and micafungin are used to treat systemic candidiasis, and caspofungin is also used in aspergillosis.

Polyenes

Amphotericin B (AmB) deoxycholate causes cell death by binding to ergosterol and damaging the fungal cytoplasmic membrane. Its use in resource-rich countries has been largely supplanted by less toxic agents. Its long half-life enables once-daily administration. CSF penetration is poor.

Adverse effects include immediate anaphylaxis, other infusion-related reactions and nephrotoxicity. Nephrotoxicity may be sufficient to require dialysis and occurs in most patients who are adequately dosed. It may be ameliorated by concomitant infusion of normal saline. Irreversible nephrotoxicity occurs with large cumulative doses of AmB.

Nystatin has a similar spectrum of antifungal activity to AmB. Its toxicity limits it to topical use, e.g. in oral and vaginal candidiasis.

Lipid formulations of amphotericin B

Lipid formulations of AmB have been developed to reduce AmB toxicity and have replaced AmB deoxycholate in many regions. They consist of AmB encapsulated in liposomes (liposomal AmB, L-AmB) or complexed with phospholipids (AmB lipid complex, ABLC). The drug becomes active on dissociating from its lipid component. Adverse effects are similar to, but considerably less frequent than, those with AmB deoxycholate, and efficacy is similar. Lipid formulations of AmB are used in invasive fungal disease, as empirical therapy in patients with neutropenic fever (p. 1327), and also in visceral leishmaniasis (p. 282).

Other antifungal agents

Flucytosine

Flucytosine (5-fluorocytosine) has particular activity against yeasts. When it is used as monotherapy, acquired resistance develops rapidly, so it should be given in combination with another antifungal agent. Adverse effects include myelosuppression, gastrointestinal upset and hepatitis.

Griseofulvin

Griseofulvin has been largely superseded by terbinafine and itraconazole for treatment of dermatophyte infections, except in children, for whom these agents remain largely unlicensed. It is deposited in keratin precursor cells, which become resistant to fungal invasion.

Terbinafine

Terbinafine distributes with high concentration to sebum and skin, with a half-life of more than 1 week. It is used topically for dermatophyte skin infections and orally for onychomycosis. The major adverse reaction is hepatic toxicity (approximately 1:50 000 cases). Terbinafine is not recommended for breastfeeding mothers.

Antiviral agents

Most viral infections in immunocompetent individuals resolve without intervention. Antiviral therapy is available for a limited number of infections only (Box 6.25).

Antiretroviral agents

These agents, used predominantly against HIV, are discussed on page 324.

Anti-herpesvirus agents

Aciclovir, valaciclovir, penciclovir and famciclovir

These antivirals are acyclic analogues of guanosine, which inhibit viral DNA polymerase after being phosphorylated by virus-derived thymidine kinase (TK). Aciclovir is poorly absorbed after oral dosing; better levels are achieved intravenously or by use of the prodrug valaciclovir. Famciclovir is the prodrug of penciclovir. Resistance is mediated by viral TK or polymerase mutations.

Ganciclovir

Chemical modification of the aciclovir molecule allows preferential phosphorylation by protein kinases of cytomegalovirus (CMV) and other β-herpesviruses (e.g. human herpesvirus (HHV) 6/7) and hence greater inhibition of the DNA polymerase, but at the expense of increased toxicity. Ganciclovir is administered intravenously or as a prodrug (valganciclovir) orally.

Cidofovir

Cidofovir inhibits viral DNA polymerases with potent activity against CMV, including most ganciclovir-resistant CMV. It also has activity against aciclovir-resistant herpes simplex virus (HSV) and varicella zoster virus (VZV), HHV6 and occasionally adenovirus, poxvirus, papillomavirus or polyoma virus, and may be used to treat these infections in immunocompromised hosts.
### Anti-influenza agents

**Zanamivir**
- **Route(s)**: Inhalation
- **Indications**: Influenza A and B
- **Significant side-effects**: Allergic reactions (very rare)

**Oseltamivir**
- **Route(s)**: Oral, IM
- **Indications**: Influenza A and B
- **Significant side-effects**: Gastrointestinal side-effects, rash, hepatitis (very rare)

**Peramivir**
- **Route(s)**: IV
- **Indications**: Influenza A and B
- **Significant side-effects**: Renal impairment, neutropenia

**Amantadine, rimantadine**
- **Route(s)**: Oral
- **Indications**: Influenza A (but see text)
- **Significant side-effects**: CNS symptoms, nausea

### Agents used in other virus infections*

**Ribavirin**
- **Route(s)**: Oral, IV, Inhalation
- **Indications**: Lassa fever (IV), RSV infection in infants (inhalation)
- **Significant side-effects**: Haemolytic anaemia, cough, dyspnoea, bronchospasm and ocular irritation (when given by inhalation)

---

*Antiviral agents used in viral hepatitis are discussed on pages 875 and 878. (AIDS = acquired immunodeficiency syndrome; CMV = cytomegalovirus; CNS = central nervous system; HIV = human immunodeficiency virus; HSV = herpes simplex virus; IM = intramuscular; IV = intravenous; RSV = respiratory syncytial virus; VZV = varicella zoster virus)*

---

### Foscarnet

This analogue of inorganic pyrophosphate acts as a non-competitive inhibitor of HSV, VZV, HHV6/7 or CMV DNA polymerase. It does not require significant intracellular phosphorylation and so may be effective when HSV or CMV resistance is due to altered drug phosphorylation. It has variable CSF penetration.

### Anti-influenza agents

**Zanamivir and oseltamivir**

These agents inhibit influenza A and B neuraminidase, which is required for release of virus from infected cells (see Fig. 6.2, p. 101). They are used in the treatment and prophylaxis of influenza. Administration within 48 hours of disease onset reduces the duration of symptoms by approximately 1–1½ days. In the UK, their use is limited mainly to adults with chronic respiratory or renal disease, significant cardiovascular disease, immunosuppression or diabetes mellitus, during known outbreaks. Peramivir has been developed as a distinct chemical structure, which means that it retains activity against some oseltamivir- and zanamivir-resistant strains. It has poor oral bioavailability and has been developed as an intravenous or intramuscular formulation for treatment of severe cases of influenza, e.g. in intensive care units. It is now approved for use in adults in a number of countries. An intravenous formulation of zanamivir is also in development for critically ill patients. Laninamivir is approved as an intranasal formulation in Japan.

### Amantadine and rimantadine

These drugs reduce replication of influenza A by inhibition of viral M2 protein ion channel function, which is required for uncoating (see Fig. 6.2). Resistance develops rapidly and is widespread, and amantadine and rimantadine should be used only if the prevalence of resistance locally is known to be low. They are no longer recommended for treatment or prophylaxis in the UK or USA, having been superseded by zanamivir and oseltamivir. However, they may still be indicated to treat oseltamivir-resistant influenza A in patients unable to take zanamivir (e.g. ventilated patients).

### Other agents used to treat viruses

Antiviral agents used to treat hepatitis B and C virus are discussed on pages 875 and 878, and those used against HIV-1 are described on page 324.
Ribavirin

Ribavirin is a guanosine analogue that inhibits nucleic acid synthesis in a variety of viruses. It is used in particular in the treatment of hepatitis C virus but also against certain viral haemorrhagic fevers, e.g. Lassa fever, although it has not been useful against Ebola virus.

Antiparasitic agents

Antimalarial agents

Artemisinin (qinghaosu) derivatives

Artemisinin originates from a herb (sweet wormwood, Artemisia annua), which was used in Chinese medicine to treat fever. Its derivatives, artemether and artemunate, were developed for use in malaria in the 1970s. Their mechanism of action is unknown. They are used in combination with other antimalarials, and are effective against strains of Plasmodium spp. that are resistant to other antimalarials. Artether is lipid-soluble and may be administered via the intramuscular and oral routes. Artesunate is water-soluble and is administered intravenously or orally. Serious adverse effects are uncommon. Artemisinin derivatives, artemether and artesunate, were developed in the 1970s. Their mechanism of action is unknown. Significant adverse effects are uncommon.

Atovaquone

Atovaquone inhibits mitochondrial function. It is an oral agent, used for treatment and prophylaxis of malaria, in combination with proguanil (see below), without which it is ineffective. It is also employed in the treatment of mild cases of Pneumocystis jiroveci pneumonia, where there is intolerance to co-trimoxazole. Significant adverse effects are uncommon.

Folate synthesis inhibitors (proguanil, pyrimethamine–sulfadoxine)

Proguanil inhibits dihydrofolate reductase and is used for malaria prophylaxis. Pyrimethamine–sulfadoxine may be used in the treatment of malaria.

Quinoline-containing compounds

Chloroquine and quinine are believed to act by intraparasitic inhibition of haem polymerisation, resulting in toxic build-up of intracellular haem. The mechanisms of action of other agents in this group (quinidine, amodiaquine, mefloquine, primaquine, etc.) may differ. They are employed in the treatment and prophylaxis of malaria. Primaquine is used for radical cure of malaria due to Plasmodium vivax and P. ovale (destruction of liver hypnozoites). Chloroquine may also be given for extra-intestinal amoebiasis. Chloroquine can cause a pruritus sufficient to compromise adherence to therapy. If used in long-term, high-dose regimens, it causes an irreversible retinopathy. Overdosage leads to life-threatening cardiotoxicity. The side-effect profile of mefloquine includes neuropsychiatric effects ranging from mood change, nightmares and agitation to hallucinations and psychosis. Quinine may cause hypoglycaemia and cardiotoxicity, especially when administered parenterally. Primaquine causes haemolysis in people with glucose-6-phosphate dehydrogenase deficiency (p. 948), which should be excluded before therapy. Chloroquine is considered safe in pregnancy but mefloquine should be avoided in the first trimester.

Lumefantrine

Lumefantrine is used in combination with artemether to treat uncomplicated falciparum malaria, including chloroquine-resistant strains. Its mechanism of action is unknown. Significant adverse effects are uncommon.

Drugs used in trypanosomiasis

Benznidazole

Benznidazole is an oral agent used to treat South American trypanosomiasis (Chagas’ disease, p. 279). Significant and common adverse effects include dose-related peripheral neuropathy, purpuric rash and granulocytopenia.

Eflornithine

Eflornithine inhibits biosynthesis of polyamines by ornithine decarboxylase inhibition, and is used in West African trypanosomiasis (T. brucei rhodesiense and gambiense). It is administered intravenously. Eflornithine treatment is associated with peripheral neuropathy and reactive arsenical encephalopathy (RAE), which carries a significant mortality.

Melarsoprol

This is an arsenical agent, used to treat central nervous system infections in East and West African trypanosomiasis (T. brucei rhodesiense and gambiense). It is administered intravenously. Melarsoprol treatment is associated with peripheral neuropathy and reactive arsenical encephalopathy (RAE), which carries a significant mortality.

Nifurtimox

Nifurtimox is administered orally to treat South American trypanosomiasis (Chagas’ disease). Gastrointestinal and neurological adverse effects are common.

Pentamidine isetionate

Pentamidine is an inhibitor of DNA replication used in West African trypanosomiasis (T. brucei gambiense) and, to a lesser extent, in visceral and cutaneous leishmaniasis. It is also prescribed in Pneumocystis jiroveci pneumonia. It is administered via intravenous or intramuscular routes. It is a relatively toxic drug, commonly causing rash, renal impairment, profound hypotension (especially on rapid infusion), electrolyte disturbances, blood dyscrasias and hypoglycaemia.

Suramin

Suramin is a naphthalene dye derivative, used to treat East African trypanosomiasis (T. brucei rhodesiense). It is administered intravenously. Adverse effects are common and include rash, gastrointestinal disturbance, blood dyscrasias, peripheral neuropathies and renal impairment.

Other antiprotozoal agents

Pentavalent antimonials

Sodium stibogluconate and meglumine antimoniate inhibit protozoal glycolysis by phosphofructokinase inhibition. They are used parenterally (intravenous or intramuscular) to treat leishmaniasis. Adverse effects include arthralgia, myalgias, raised hepatic transaminases, pancreatitis and electrocardiogram changes. Severe cardiotoxicity leading to death is not uncommon.
**Diloxanide furoate**
This oral agent is used to eliminate luminal cysts following treatment of intestinal amoebiasis, or in asymptomatic cyst excreters. The drug is absorbed slowly (enabling luminal persistence) and has no effect in hepatic amoebiasis. It is a relatively non-toxic drug, the most significant adverse effect being flatulence.

**Iodoquinol** (di-iodohydroxyquinoline)
Iodoquinol is a quinoline derivative (p. 128) with activity against Entamoeba histolytica cysts and trophozoites. It is used orally to treat asymptomatic cyst excreters or, in association with another amoebicide (e.g. metronidazole), to treat extra-intestinal amoebiasis. Long-term use of this drug is not recommended, as neurological adverse effects include optic neuritis and peripheral neuropathy.

**Nitazoxanide**
Nitazoxanide is an inhibitor of pyruvate–ferredoxin oxidoreductase-dependent anaerobic energy metabolism in protozoa. It is a broad-spectrum agent, active against various nematodes, tapeworms, flukes and intestinal protozoa. Nitazoxanide also has activity against some anaerobic bacteria and viruses. It is administered orally in giardiasis and cryptosporidiosis. Adverse effects are usually mild and involve the gastrointestinal tract (e.g. nausea, diarrhoea and abdominal pain).

**Paromomycin**
Paromomycin is an aminoglycoside (p. 122) that is used to treat visceral leishmaniasis and intestinal amoebiasis. It is not significantly absorbed when administered orally, and is therefore given orally for intestinal amoebiasis and by intramuscular injection for leishmaniasis. It showed early promise in the treatment of HIV-associated cryptosporidiosis but subsequent trials have demonstrated that this effect is marginal at best.

**Drugs used against helminths**

**Benzimidazoles (albendazole, mebendazole)**
These agents act by inhibiting both helminth glucose uptake, causing depletion of glycogen stores, and fumarate reductase. Albendazole is used for hookworm, ascarisiasis, threadworm, Strongyloides infection, trichinella, Taenia solium (cysticercosis) and hydatid disease. Mebendazole is used for hookworm, ascarisiasis, threadworm and whipworm. The drugs are administered orally. Absorption is relatively poor but is increased by a fatty meal. Significant adverse effects are uncommon.

**Bithionol**
Bithionol is used to treat fluke infections with Fasciola hepatica. It is well absorbed orally. Adverse effects are mild (e.g. nausea, vomiting, diarrhoea, rashes) but relatively common (approximately 30%).

**Diethylcarbamazine**
Diethylcarbamazine (DEC) is an oral agent used to treat filariasis and loiasis. Treatment of filariasis is often followed by fever, headache, nausea, vomiting, arthralgia and prostration. This is caused by the host response to dying microfilariae, rather than the drug, and may be reduced by pre-treatment with glucocorticoids.

**Ivermectin**
Ivermectin binds to helminth nerve and muscle cell ion channels, causing increased membrane permeability. It is an oral agent, used in Strongyloides infection, filariasis and onchocerciasis. Significant side-effects are uncommon.

**Niclosamide**
Niclosamide inhibits oxidative phosphorylation, causing paralysis of helminths. It is an oral agent, used in Taenia saginata and intestinal T. solium infection. Systemic absorption is minimal and it has few significant side-effects.

**Piperazine**
Piperazine inhibits neurotransmitter function, causing helminth muscle paralysis. It is an oral agent, used in ascarisiasis and threadworm (Enterobius vermicularis) infection. Significant adverse effects are uncommon but include neuropsychological reactions such as vertigo, delirium and convulsions.

**Praziquantel**
Praziquantel increases membrane permeability to Ca2+, causing violent contraction of worm muscle. It is the drug of choice for schistosomiasis and is also used in T. saginata, T. solium (cysticercosis) and fluke infections (Clonorchis, Paragonimus) and in echinococcosis. It is administered orally and is well absorbed. Adverse effects are usually mild and transient, and include nausea and abdominal pain.

**Pyrantel pamoate**
This agent causes spastic paralysis of helminth muscle through a suxamethonium-like action. It is used orally in ascarisiasis and threadworm infection. Systemic absorption is poor and adverse effects are uncommon.

**Thiabendazole**
Thiabendazole inhibits fumarate reductase, which is required for energy production in helminths. It is used orally in Strongyloides infection and topically to treat cutaneous larva migrans. Significant adverse effects are uncommon.

## Comprehensive evaluation of the poisoned patient 132

### General approach to the poisoned patient 134
- Triage and resuscitation 134
- Clinical assessment and investigations 134
- Psychiatric assessment 135
- General management 135

### Poisoning by specific pharmaceutical agents 137
- Analgesics 137
- Antidepressants 138
- Cardiovascular medications 140
- Iron 140
- Antipsychotic drugs 141
- Antidiabetic agents 141
- Pharmaceutical agents less commonly taken in poisoning 141

### Drugs of misuse 141
- Depressants 141
- Stimulants and entactogens 143
- Hallucinogens 143
- Dissociative drugs 144
- Volatile substances 144
- Body packers and body stuffers 144

## Chemicals and pesticides 144
- Carbon monoxide 144
- Organophosphorus insecticides and nerve agents 145
- Carbamate insecticides 146
- Paraquat 147
- Methanol and ethylene glycol 147
- Corrosive substances 147
- Aluminium and zinc phosphide 148
- Copper sulphate 148
- Chemicals less commonly taken in poisoning 148
- Chemical warfare agents 149

### Environmental poisoning 149

### Food-related poisoning 149

### Plant poisoning 150
## Comprehensive evaluation of the poisoned patient

1. **Airway, breathing, circulation**
   - Respiration rate, oxygen saturation, pulse, BP, dysrhythmias

2. **Level of consciousness**
   - Presence of seizures, delirium, agitation or psychosis

3. **Chest**
   - Evidence of aspiration, bronchoconstriction

4. **Movement and muscles**
   - Tone, fasciculations, myoclonus, tremor, paralysis, ataxia

5. **Reflexes**
   - Tendon reflexes, plantar responses, inducible clonus

6. **Eyes**
   - Miosis or mydriasis, diplopia or strabismus, lacrimation

7. **Abdomen**
   - Hepatic or epigastric tenderness, ileus, palpable bladder

8. **Skin**
   - Temperature, cyanosis, flushing, sweating, blisters, pressure areas, piloerection, evidence of self-harm

9. **Mouth**
   - Dry mouth, excessive salivation

10. **Psychiatric evaluation**
    - Features of psychiatric illness, mental capacity

---

### Taking a history in poisoning

- What toxin(s) have been taken and how much?
- What time were they taken and by what route?
- Has alcohol or any other substance (or substances, including drugs of misuse) been taken as well?
- Obtain details from witnesses (e.g. family, friends, ambulance personnel) of the circumstances of the overdose
- Assess immediate suicide risk in those with apparent self-harm (full psychiatric evaluation when patient has recovered physically)
- Assess capacity to make decisions about accepting or refusing treatment
- Establish past medical history, drug history and allergies, social and family history
- Record all information carefully
Comprehensive evaluation of the poisoned patient

Clinical signs of poisoning by pharmaceutical agents and drugs of misuse:

- **Pupil size**
  - Small: opioids, clonidine, organophosphorus compounds
  - Large: tricyclic antidepressants, amphetamines, cocaine

- **Respiratory rate**
  - Reduced: opioids, benzodiazepines
  - Increased: salicylates

- **Blood pressure**
  - Hypotension: tricyclic antidepressants, haloperidol
  - Hypertension: cocaine, α-adrenoceptor agonists

- **Right upper quadrant /renal angle tenderness**
  - Paracetamol hepatotoxicity, renal toxicity

- **Epigastric tenderness**
  - NSAIDs, salicylates

- **Rhabdomyolysis**
  - Amphetamines, caffeine

- **Cerebellar signs**
  - Some anticonvulsants, alcohol

- **Extrapyramidal signs**
  - Phenothiazines, haloperidol, metoclopramide

- **Cyanosis**
  - Any CNS depressant drug or agent (N.B. consider methaemoglobinaemia caused by dapsone, amyl nitrite etc.)

- **Tachycardia or tachyarrhythmias**: tricyclic antidepressants, theophylline, digoxin, antihistamines

- **Bradycardia or bradyarrhythmias**: digoxin, β-blockers, calcium channel blockers, opioids, organophosphates

- **Hyperthermia and sweating**: ecstasy, serotonin re-uptake inhibitors, salicylates

- **Hypothermia**: any CNS depressant drug, opioids, chlorpromazine

- **Needle tracks**
  - Drugs of misuse: opioids etc.

- **Body temperature**
  - Hyperthermia and sweating: ecstasy, serotonin re-uptake inhibitors, salicylates
  - Hypothermia: any CNS depressant drug, opioid, chlorpromazine

- **Blood pressure**
  - Hypotension: tricyclic antidepressants, haloperidol
  - Hypertension: cocaine, α-adrenoceptor agonists

- **Respiratory rate**
  - Tachypnoea: tricyclic antidepressants, theophylline, digoxin, antihistamines
  - Bradypnoea: digoxin, β-blockers, calcium channel blockers, opioids, organophosphates

- **Blood**
  - Haemodialysis
  - Haemoperfusion

- **Kidneys**
  - Urinary alkalinisation

- **Gastrointestinal tract**
  - Multiple-dose activated charcoal

**Decontamination and enhanced elimination.** One of the key aspects in the evaluation of a poisoned patient is deciding if decontamination and/or enhanced elimination is required.
Acute poisoning is common, accounting for about 1% of hospital admissions in the UK. Common or otherwise important substances involved are shown in Box 7.1. In developed countries, the most frequent cause is intentional drug overdose in the context of self-harm, often involving prescribed or ‘over-the-counter’ medicines. Accidental poisoning is also common, especially in children and the elderly (Box 7.2). Toxicity also results from alcohol or recreational substance use, or following occupational or environmental exposure. Poisoning is a major cause of death in young adults, but most deaths occur before patients reach medical attention, and mortality is low (<1%) in those admitted to hospital.

In developing countries, the frequency of self-harm is more difficult to estimate. Because of their widespread availability and use, household and agricultural products, such as pesticides and herbicides, are common sources of poisoning and have a much higher case fatality. In China and South-east Asia, pesticides account for about 300,000 suicides each year.snake bite and other forms of envenomation are also important causes of morbidity and mortality internationally and are discussed in Chapter 8.

### 7.1 Important substances involved in poisoning

#### In the UK
- Analgesics: paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs)
- Antidepressants: tricyclic antidepressants (TCAs), selective serotonin re-uptake inhibitors (SSRIs) and lithium
- Cardiovascular agents: β-blockers, calcium channel blockers and cardiac glycosides
- Drugs of misuse: depressants (e.g. opiates, benzodiazepines), stimulants and entactogens (e.g. amphetamines, MDA, mephedrone, cocaine), hallucinogens (e.g. cannabis, synthetic cannabinoids, receptor agonists, LSD)
- Carbon monoxide
- Alcohol

#### In South and South-east Asia
- Organophosphorus and carbamate insecticides
- Aluminium and zinc phosphate
- Oleander
- Corrosives
- Snake venoms (Ch. 8)

### 7.2 Poisoning in old age

- **Aetiology:** may result from accidental poisoning (e.g. due to delirium or dementia) or drug toxicity as a consequence of impaired renal or hepatic function or drug interaction. Toxic prescription medicines are more likely to be available.
- **Psychiatric illness:** self-harm is less common than in younger adults but more frequently associated with depression and other psychiatric illness, as well as chronic illness and pain. There is a higher risk of subsequent suicide.
- **Severity of poisoning:** increased morbidity and mortality result from reduced renal and hepatic function, lower functional reserve, increased sensitivity to sedative agents and frequent comorbidity.

### 7.3 Substances of very low toxicity

- Writing/educational materials, e.g. pencil lead, crayons, chalk
- Decorating products, e.g. emulsion paint, wallpaper paste
- Cleaning/bathroom products (except dishwasher tablets and liquid laundry detergent capsules, which can be corrosive)
- Pharmaceuticals: oral contraceptives, most antibiotics (but not tetracyclines or antituberculous drug), vitamins B, C and E, prednisolone, emollients and other skin creams, baby lotion
- Miscellaneous: plasticine, silica gel, most household plants, plant food, pet food, soil

### General approach to the poisoned patient

A general approach is shown on pages 132–133. In many countries, poisoning centres are available to provide advice on management of suspected poisoning with specific substances. Information is also available online (p. 150).

### Triage and resuscitation

Patients who are seriously poisoned must be identified early so that appropriate management is not delayed. Triage involves:
- immediately assessing vital signs
- identifying the poison(s) involved and obtaining adequate information about them
- identifying patients at risk of further attempts at self-harm and removing any remaining hazards.

Those with possible external contamination with chemical or environmental toxins should undergo appropriate decontamination (p. 133). Critically ill patients must be resuscitated (p. 174).

The Glasgow Coma Scale (GCS) is commonly employed to assess conscious level, although not specifically validated in poisoning. The AVPU (alert/verbal/painful/unresponsive) scale is also a rapid and simple method. An electrocardiogram (ECG) should be performed and cardiac monitoring instituted in all patients with cardiovascular features or where exposure to potentially cardiotoxic substances is suspected. Patients who may need antidotes should be weighed if possible, so that appropriate weight-related doses can be prescribed.

Substances unlikely to be toxic in humans should be identified so that inappropriate admission and intervention are avoided (Box 7.3).

### Clinical assessment and investigations

History and examination are described on page 132. Occasionally, patients may be unaware of or confused about what they have taken, or may exaggerate (or, less commonly, underestimate) the size of the overdose, but rarely mislead medical staff deliberately. In regions of the world where self-poisoning is illegal, patients may be reticent about giving a history.

Toxic causes of abnormal physical signs are shown on page 133. The patient may have a cluster of clinical features (“toxidrome”) suggestive of poisoning with a particular drug type, e.g. anticholinergic, serotoninergic (see Box 7.10), stimulant, sedative, opioid (see Box 7.12) or cholinergergic (see Box 7.14) feature clusters. Poisoning is a common cause of coma, especially with substances such as sedatives, hypnotics, alcohol, antihistamines and general anaesthetics.
in younger people, but it is important to exclude other potential causes (p. 194).

Urea, electrolytes and creatinine should be measured in all patients with suspected systemic poisoning. Arterial blood gases should be checked in those with significant respiratory or circulatory compromise, or after poisoning with substances likely to affect acid–base status (Box 7.4). Calculation of anion and osmolar gaps may help to inform diagnosis and management (Box 7.5). Potent oxidising agents may cause methaemoglobinaemia, with consequent blue discoloration of skin and blood, and reduced oxygen delivery to the tissues (Fig. 7.1).

For some substances, management may be facilitated by measurement of the amount of toxin in the blood. Qualitative urine screens for potential toxins, including near-patient testing kits, have a limited clinical role.

### Psychiatric assessment

Patients presenting with drug overdose in the context of self-harm should undergo psychiatric evaluation prior to discharge by a health professional with appropriate training (p. 1187). This should occur after they have recovered from poisoning, unless there is an urgent issue, such as uncertainty about their capacity to decline medical treatment.

### General management

Patients presenting with eye/skin contamination should undergo local decontamination measures. These are described on page 133.

### Gastrointestinal decontamination

Patients who have ingested potentially life-threatening quantities of toxins may be considered for gastrointestinal decontamination if poisoning has been recent (p. 133).
Activated charcoal

Given orally as a slurry, activated charcoal absorbs toxins in the bowel as a result of its large surface area. It can prevent absorption of an important proportion of the ingested dose of toxin, but efficacy decreases with time and current guidelines do not encourage use more than 1 hour after overdose, unless a sustained-release preparation has been taken or when gastric emptying may be delayed. Use is ineffective for some toxins that do not bind to activated charcoal (Box 7.6). In patients with impaired swallowing or a reduced level of consciousness, activated charcoal, even via a nasogastric tube, carries a risk of aspiration pneumonitis, which can be reduced (but not eliminated) by protecting the airway with a cuffed endotracheal tube.

Multiple doses of oral activated charcoal (50 g 6 times daily in an adult) may enhance the elimination of some substances at any time after poisoning (Box 7.7). This interrupts enterohepatic circulation or reduces the concentration of free drug in the gut lumen, to the extent that drug diffuses from the blood back into the bowel to be absorbed on to the charcoal (‘gastrointestinal dialysis’). A laxative is generally given with the charcoal to reduce the risk of constipation or intestinal obstruction by charcoal ‘briquette’ formation in the gut lumen.

Evidence suggests that single or multiple doses of activated charcoal do not improve clinical outcomes after poisoning with pesticides or oleander.

Gastric aspiration and lavage

Gastric aspiration and/or lavage is very infrequently indicated in acute poisoning, as it is no more effective than activated charcoal for most substances and complications are common, especially pulmonary aspiration. It is contraindicated if strong acids, alkalis or petroleum distillates have been ingested. Use may be justified for life-threatening overdoses of those substances that are not absorbed by activated charcoal (see Box 7.6).

Whole bowel irrigation

This involves the administration of large quantities of osmotically balanced polyethylene glycol and electrolyte solution (1–2 L/hr for an adult), usually by a nasogastric tube, until the rectal effluent is clear. It is occasionally indicated to enhance the elimination of ingested packets of illicit drugs or slow-release tablets such as iron and lithium that are not absorbed by activated charcoal. Contraindications include inadequate airway protection, haemodynamic instability, gastrointestinal haemorrhage, obstruction or ileus. Whole bowel irrigation may precipitate nausea and vomiting, abdominal pain and electrolyte disturbances.

Urinary alkalisation

Urinary excretion of weak acids and bases is affected by urinary pH, which changes the extent to which they are ionised. Highly ionised molecules pass poorly through lipid membranes and therefore little tubular reabsorption occurs and urinary excretion is increased. If the urine is alkalinised (pH > 7.5) by the administration of sodium bicarbonate (e.g. 1.5 L of 1.26% sodium bicarbonate over 2 hrs), weak acids (e.g. salicylates, methotrexate) are highly ionised, resulting in enhanced urinary excretion.

Urinary alkalisation is currently recommended for patients with clinically significant salicylate poisoning when the criteria for haemodialysis are not met (see below). It is also sometimes used for poisoning with methotrexate. Complications include alkalaemia, hypokalaemia and occasionally alkalotic tetany (p. 367). Hypokalaemia may occur but is rare.

Haemodialysis and haemoperfusion

These techniques can enhance the elimination of poisons that have a small volume of distribution and a long half-life after overdose; use is appropriate when poisoning is sufficiently severe. The toxin must be small enough to cross the dialysis membrane (haemodialysis) or must bind to activated charcoal (haemoperfusion) (see Box 7.7). Haemodialysis can also correct acid–base and metabolic disturbances associated with poisoning (p. 135).

Lipid emulsion therapy

Lipid emulsion therapy is increasingly used for poisoning with lipid-soluble agents, such as local anaesthetics, tricyclic antidepressants, calcium channel blockers and lipid-soluble β-adrenoceptor antagonists (β-blockers) such as propranolol. It involves intravenous infusion of 20% lipid emulsion (e.g. Intralipid, suggested initial dose 1.5 mL/kg, followed by a continued infusion of 0.25 mL/kg/min until there is clinical improvement). It is thought that lipid-soluble toxins partition into the intravenous lipid, reducing target tissue concentrations. The elevated myocardial free fatty acid concentrations may also have beneficial effects on myocardial metabolism and performance by counteracting the inhibition of myocardial fatty acid oxidation produced by some cardiotoxins, enabling increased adenosine triphosphate (ATP) synthesis and energy production. Some animal studies have suggested efficacy and case reports of use in human poisoning have also been

Poisoning by specific pharmaceutical agents

Analgesics

Paracetamol

Paracetamol (acetaminophen) is the drug most commonly used in overdose in the UK. Toxicity is caused by an intermediate reactive metabolite that binds covalently to cellular proteins,
causing cell death. This results in hepatic and occasionally renal failure. In therapeutic doses, the toxic metabolite is detoxified in reactions requiring glutathione, but in overdose, glutathione reserves become exhausted.

**Management**

Activated charcoal may be used in patients presenting within 1 hour. Antidotes for paracetamol act by replenishing hepatic glutathione and should be administered to all patients with acute poisoning and paracetamol concentrations above a ‘treatment line’ provided on paracetamol poisoning nomograms (Fig. 7.2). The threshold used for these nomograms varies between countries, however, and local guidance should be followed. Acetylcysteine given intravenously (or orally in some countries) is highly efficacious if administered within 8 hours of the overdose. However, efficacy declines thereafter, so administration should not be delayed in patients presenting after 8 hours to await a paracetamol blood concentration result. The antidote can be stopped if the paracetamol concentration is shown to be below the nomogram treatment line. Liver and renal function, International Normalised Ratio (INR) and a venous bicarbonate should also be measured. Arterial blood gases and lactate should be assessed in patients with reduced bicarbonate or severe liver function abnormalities; metabolic acidosis indicates severe poisoning.

Anaphylactoid reactions are the most important adverse effects of acetylcysteine and are related to dose-related histamine release. Common features are itching and urticaria, and in severe cases, bronchospasm and hypotension. Most cases can be managed by temporary discontinuation of acetylcysteine and administration of an antihistamine.

An alternative antidote is methionine 2.5 g orally (adult dose) every 4 hours to a total of four doses, but this may be less effective, especially after delayed presentation. Liver transplantation should be considered for paracetamol poisoning with life-threatening liver failure (p. 856). If multiple ingestions of paracetamol have taken place over several hours (‘staggered overdose’) or days (e.g. chronic therapeutic excess), acetylcysteine may be indicated; specific treatment recommendations vary between countries.

**Salicylates (aspirin)**

**Clinical features**

Salicylate overdose commonly causes nausea, vomiting, sweating, tinnitus and deafness. Direct stimulation of the respiratory centre produces hyperventilation and respiratory alkalosis. Peripheral vasodilatation with bounding pulses and profuse sweating occurs in moderately severe cases. Serious poisoning is associated with metabolic acidosis, hypoprothrombinaemia, hyperglycaemia, hyperpyrexia, renal failure, pulmonary oedema, shock and cerebral oedema. Agitation, delirium, coma and fits may occur, especially in children. Toxicity is enhanced by acidosis, which increases salicylate transfer across the blood–brain barrier.

**Management**

Activated charcoal should be administered if the patient presents within 1 hour. Multiple doses may enhance salicylate elimination but are not routinely recommended.

The plasma salicylate concentration should be measured at least 2 (symptomatic patients) or 4 hours (asymptomatic patients) after overdose and repeated in suspected serious poisoning, as concentrations may continue to rise for several hours. Clinical status, however, is more important than the salicylate concentration when assessing severity.

Dehydration should be corrected carefully because of the risk of pulmonary oedema. Metabolic acidosis should be treated with intravenous sodium bicarbonate (8.4%), after plasma potassium has been corrected. Urinary alkalisation is indicated for adults with salicylate concentrations above 500 mg/L. Haemodialysis is very effective for removing salicylate and correcting associated acid–base and fluid balance abnormalities. It should be considered when serum concentrations are above 700 mg/L in adults with severe toxic features, or in renal failure, pulmonary oedema, coma, convulsions or refractory acidosis.

**Non-steroidal anti-inflammatory drugs**

**Clinical features**

Overdose of most non-steroidal anti-inflammatory drugs (NSAIDs) usually causes only minor abdominal discomfort, vomiting and/or diarrhoea, but convulsions can occur occasionally, especially with mefenamic acid. Coma, prolonged seizures, apnoea, liver dysfunction and renal failure may follow substantial overdose but are rare. Features of toxicity are unlikely to develop in patients who are asymptomatic more than 6 hours after overdose.

**Management**

Electrolytes, liver function tests and a full blood count should be checked in all but the most trivial cases. Activated charcoal may be given if the patient presents within 1 hour. Symptomatic treatment for nausea and gastrointestinal irritation may be needed.

**Antidepressants**

**Tricyclic antidepressants**

Overdose with tricyclic antidepressants (TCAs) carries a high morbidity and mortality because of their sodium channel-blocking, anticholinergic and α-adrenoceptor-blocking effects.

**Clinical features**

Anticholinergic effects are common (Box 7.10). Severe complications include convulsions, coma and arrhythmias (ventricular
tachycardia, ventricular fibrillation and, less commonly, heart block). Hypotension results from inappropriate vasodilatation or impaired myocardial contractility. Serious complications appear more common with dosulepin and amitriptyline.

Management

Activated charcoal should be administered if the patient presents within 1 hour. A 12-lead ECG should be taken and continuous cardiac monitoring maintained for at least 6 hours. Prolongation of the QRS interval (especially if >0.16 secs) indicates severe sodium channel blockade and a high risk of arrhythmia (Fig. 7.3). QT interval prolongation may also occur. Arterial blood gases should be measured in suspected severe poisoning.

In patients with arrhythmias, significant QRS or QT prolongation with intravenous fluids. Seizures should be treated initially with intravenous benzodiazepines (see Box 7.8).

Selective serotonin and noradrenaline re-uptake inhibitors

Selective serotonin re-uptake inhibitor (SSRI) antidepressants (e.g. fluoxetine, paroxetine, fluvoxamine, sertraline, citalopram, escitalopram) are increasingly used to treat depression and are less toxic in overdose than TCAs. The related serotonin–noradrenaline re-uptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are also commonly used but are more toxic than SSRIs in overdose.

Clinical features and management

Overdose of SSRIs may produce nausea and vomiting, tremor, insomnia and sinus tachycardia. Agitation, drowsiness and convulsions occur infrequently and may be delayed for several hours. Serotonin syndrome may occur (see Box 7.10), especially if SSRIs are taken in combination with other serotonergic agents. Cardiac arrhythmias occur infrequently and most patients require supportive care only. The toxic effects of SNRIs are similar but tachycardia, hypertension or hypotension and ECG changes (QRS and QT prolongation) may be more prominent and hypoglycaemia can also arise.

Lithium

Severe lithium toxicity is uncommon after intentional acute overdose but is more often encountered in patients taking therapeutic doses, frequently as a result of interactions with drugs such as diuretics or NSAIDs. Severe toxicity is more common after acute overdose in patients already taking chronic therapy (‘acute on chronic’ poisoning).

Clinical features

Nausea, diarrhoea, polyuria, dizziness and tremor may progress to muscular weakness, drowsiness, delirium, myoclonus, fasciculations, choreoathetosis and renal failure. Coma, seizures, ataxia, cardiac dysrhythmias such as heart block, blood pressure disturbances and renal failure may occur in severe poisoning.

Management

Activated charcoal is ineffective. Early gastric lavage is of theoretical benefit, but lithium tablets are likely to remain intact in the stomach and may be too large for aspiration via a lavage tube. Whole bowel irrigation is often used after substantial overdose but efficacy is unproven.

Lithium concentrations should be measured immediately (symptomatic patients) or after at least 6 hours (asymptomatic patients) following acute overdose. The usual therapeutic range is 0.4–1.0 mmol/L. Adequate hydration should be maintained with intravenous fluids. Seizures should be treated as in Box 7.8.

Haemodialysis should be considered for severe toxicity associated with high lithium concentrations (e.g. >4.0 mmol/L after chronic or ‘acute on chronic’ poisoning, or >7.5 mmol/L after acute poisoning). Lithium concentrations are reduced substantially during dialysis, but rebound increases occur after discontinuation and multiple sessions are usually required.
Cardiovascular medications

Although not common, cardiovascular drug overdose is important because features of toxicity are often severe.

Beta-blockers

Major features of toxicity are bradycardia and hypotension; heart block, pulmonary oedema and cardiogenic shock occur in severe poisoning. Those with additional sodium channel-blocking effects (e.g. propranolol, acebutolol, carvedilol) may cause seizures, delirium and coma, while sotalol, which also blocks potassium channels, may cause QT prolongation and torsades de pointes (Box 7.8 and p. 476).

Management

Intravenous fluids may reverse hypotension but care is required to avoid pulmonary oedema. Bradycardia and hypotension may respond to high doses of atropine (up to 3 mg in an adult) or an infusion of isoproterenol. Glucagon (5–10 mg over 10 mins, then 1–5 mg/hr by infusion) counteracts β-blockade by stimulating intracellular cyclic adenosine monophosphate (cAMP) production and is now more commonly used. In severe cases, ‘hyperinsulinaemia euglycaemic therapy’ has been used, as described under calcium channel blockers below. The efficacy of lipid emulsion therapy in severe poisoning with lipid-soluble β-blockers, such as propranolol, carvedilol and oxprenolol, is uncertain.

Calcium channel blockers

L-type calcium channel blockers are highly toxic in overdose. Dihydropyridines (e.g. nifedipine, amlodipine) cause vasodilatation, whereas diltiazem and verapamil have predominantly cardiac effects, including bradycardia and reduced myocardial contractility.

Clinical features

Hypotension due to vasodilatation or myocardial depression is common and bradycardias and heart block may also occur, especially with verapamil and diltiazem. Gastrointestinal disturbances, delirium, metabolic acidosis, hyperglycaemia and hyperkalaemia may also be present.

Management

Hypotension should be corrected with intravenous fluids, taking care to avoid pulmonary oedema. Persistent hypotension may respond to intravenous calcium gluconate (10 mg IV over 5 mins, repeated as required). Isoproterenol and glucagon may also be useful. Successful use of intravenous insulin with glucose (10–20% dextrose with insulin initially at 0.5–2.0 U/kg/hr, increasing to 5–10 U/kg/hr according to clinical response), so-called ‘hyperinsulinaemia euglycaemic therapy’, has been reported in patients unresponsive to other strategies. The mechanism of action remains to be fully elucidated, but in states of shock myocardial metabolism switches from use of free fatty acids to glucose. Calcium channel blocker poisoning is also associated with hypoinsulinaemia and insulin resistance, impeding glucose uptake by myocytes. High doses of insulin inhibit lipolysis and increase glucose uptake and the efficiency of glucose utilisation. Cardiac pacing may be needed for severe unresponsive bradycardias or heart block. Lipid emulsion therapy has also been used in severe poisoning with apparent benefit, although evidence is largely anecdotal.

Digoxin and oleander

Poisoning with digoxin is usually accidental, arising from prescription of an excessive dose, impairment of renal function or drug interactions. In South Asia, deliberate self-poisoning with yellow oleander (Thevetia peruviana), containing cardiac glycosides, is common.

Clinical features

Cardiac effects include tachyarrhythmias (either atrial or ventricular) and bradycardias, with or without atrioventricular block. Ventricular bigeminy is common and atrial tachycardia with evidence of atrioventricular block is highly suggestive of the diagnosis. Severe poisoning is often associated with hyperkalaemia. Non-cardiac features include delirium, headache, nausea, vomiting, diarrhoea and (rarely) altered colour vision. Digoxin poisoning can be confirmed by elevated plasma concentration (usual therapeutic range 1.3–2.5 mmol/L). After chronic exposure, concentrations >5 mmol/L suggest serious poisoning.

Management

Activated charcoal is commonly administered to patients presenting soon after acute ingestion, although evidence of benefit is lacking. Urea, electrolytes and creatinine should be measured, a 12-lead ECG performed and cardiac monitoring instituted. Hypoxia, hypokalaemia (sometimes caused by concurrent diuretic use), hypomagnesaemia and acidosis increase the risk of arrhythmias and should be corrected. Significant bradycardias may respond to atropine, although temporary pacing is sometimes needed. Ventricular arrhythmias may respond to intravenous magnesium (see Box 7.8). If available, digoxin-specific antibody fragments should be administered when there are severe refractory ventricular arrhythmias or bradycardias. These are effective for both digoxin and yellow oleander poisoning.

Iron

Overdose with iron can cause severe and sometimes fatal poisoning, with toxicity of individual iron preparations related to their elemental iron content.

Clinical features

Early features include gastrointestinal disturbance with the passage of grey or black stools, progressing to hyperglycaemia, leukocytosis, haematemesis, rectal bleeding, drowsiness, convulsions, coma, metabolic acidosis and cardiovascular collapse in severe cases. Early symptoms may improve or resolve within 6–12 hours, but hepatocellular necrosis can develop 12–24 hours after overdose and occasionally progresses to hepatic failure. Gastrointestinal strictures are late complications.

Management

Activated charcoal is ineffective but gastric lavage may be considered in patients presenting soon after substantial overdose, although efficacy is unknown. Serum iron concentration should be measured at least 4 hours after overdose or earlier if there are features of toxicity. Desferrioxamine chelates iron and should be administered immediately in patients with severe features, without waiting for serum iron concentrations, as well as symptomatic patients with high serum iron concentrations (e.g. >5 mg/L). Desferrioxamine may cause hypotension, allergic reactions and occasionally pulmonary oedema. Otherwise, treatment is supportive and directed at complications.
Antipsychotic drugs

Antipsychotic drugs (p. 1198) are often prescribed for patients at high risk of self-harm or suicide and are often taken in overdose.

Clinical features

Anticholinergic features (see Box 7.10) including drowsiness, tachycardia and hypotension, are common and convulsions may occur. Acute dystonias, including oculogyric crisis, torticollis and trismus, may occur after overdose with typical antipsychotics like haloperidol or chlorpromazine. QT interval prolongation and torsades de pointes can occur with some typical (e.g. haloperidol) and atypical (e.g. quetiapine, amisulpride, ziprasidone) agents.

Management

Activated charcoal may be of benefit if given early. Cardiac monitoring should be undertaken for at least 6 hours. Management is largely supportive, with treatment directed at complications (see Box 7.8).

Antidiabetic agents

Overdose is uncommon but toxic effects can be severe.

Clinical features

Sulphonylureas, meglitinides (e.g. nateglinide, repaglinide) and parenteral insulin cause hypoglycaemia when taken in overdose, although insulin is non-toxic if ingested by mouth. The duration of hypoglycaemia depends on the half-life or release characteristics of the preparation and may be prolonged over several days with long-acting agents such as glibenclamide, insulin zinc suspension or insulin glargine.

Features of hypoglycaemia include nausea, agitation, sweating, aggression, delirium, tachycardia, hypothermia, drowsiness, convulsions and coma (p. 738). Permanent neurological damage can occur if hypoglycaemia is prolonged. Hypoglycaemia can be diagnosed using bedside glucose strips but venous blood can be sent for laboratory confirmation.

Metformin is uncommonly associated with hypoglycaemia. Its major toxic effect is lactic acidosis, which can have a high mortality, and is particularly common in older patients and those with renal or hepatic impairment, or when ethanol has been co-ingested. Other features of metformin overdose are nausea, vomiting, diarrhoea, abdominal pain, drowsiness, coma, hypotension and cardiovascular collapse.

There is limited experience of overdose involving thiazolidinediones (e.g. pioglitazone) and dipeptidyl peptidase 4 (DPP-4) inhibitors (e.g. sitagliptin) but significant hypoglycaemia is unlikely.

Management

Activated charcoal should be considered for recent substantial overdose. Venous blood glucose and urea and electrolytes should be measured and measurement repeated regularly. Hypoglycaemia should be corrected using oral or intravenous glucose (50 mL of 50% dextrose); an infusion of 10–20% dextrose may be required to prevent recurrence. Intramuscular glucagon can be used as an alternative, especially if intravenous access is unavailable. Failure to regain consciousness within a few minutes of normalisation of the blood glucose can indicate that a central nervous system (CNS) depressant has also been ingested, the hypoglycaemia has been prolonged, or there is another cause of coma (e.g. cerebral haemorrhage or oedema).

Arterial blood gases and plasma lactate should be taken after metformin overdose; acidosis should be corrected with intravenous sodium bicarbonate (250 mL 1.26% solution or 50 mL 8.4% solution, repeated as necessary). In severe cases, haemodialysis or haemodiafiltration is used.

Pharmaceutical agents less commonly taken in poisoning

An overview of the clinical features and management for drugs less commonly involved in poisoning is provided in Box 7.11.

Drugs of misuse

Drugs of misuse are common causes of toxicity requiring hospital admission. Management has recently become more complex because of the emergence of ‘novel psychoactive substances’ (NPS). These are often chemically related to traditional drugs of misuse, but with structural modifications made to evade legal control. The constituents of branded NPS products are often unknown and knowledge about the clinical features and management of NPS toxicity is limited.

Depressants

These produce CNS depression, including drowsiness, ataxia, delirium and coma, sometimes with respiratory depression, airway compromise, aspiration pneumonia and respiratory arrest.
Physical dependence occurs within a few weeks of regular high-dose use. Withdrawal can start within 12 hours, causing intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Commonly encountered opioids and clinical features of poisoning are shown in Box 7.12. Needle tracks may be visible in intravenous users and there may be drug-related paraphernalia. Methadone may also cause QTc prolongation and torsades de pointes. Features of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents such as methadone or oxycodone.

Use of the specific opioid antagonist naloxone (0.4–2 mg IV in an adult, repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in chronic opiate users and breakthrough pain in those receiving opioids for pain management. Repeated doses or an infusion are often required because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. Patients should be monitored for at least 6 hours after the last naloxone dose. Rare complications of naloxone therapy include fits, ventricular arrhythmias and pulmonary oedema.

(Box 7.12). Other complications of coma include pressure blisters or sores and rhabdomyolysis. Effects are potentiated by other CNS depressants, including alcohol.

Essential supportive care is detailed in Box 7.8. Antidotes are available for some depressants.

### Benzodiazepines

Benzodiazepines (e.g. diazepam) and related substances (e.g. zopiclone) are of low toxicity when taken alone in overdose but can enhance CNS and respiratory depression when taken with other sedative agents, including alcohol. They are more hazardous in the elderly and those with chronic lung or neuromuscular disease (see Box 7.12).

The specific benzodiazepine antagonist flumazenil (0.5 mg IV, repeated if needed) increases conscious level in patients with benzodiazepine overdose, but carries a risk of seizures and is contraindicated in patients co-ingesting pro-convulsants (e.g. TCAs) and those with a history of epilepsy.

### Opioids

Toxicity may result from misuse of illicit drugs such as heroin or from intentional or accidental overdose of medicinal opiates. Intravenous or smoked heroin gives a rapid, intensely pleasurable experience, often accompanied by heightened sexual arousal. Physical dependence occurs within a few weeks of regular high-dose use. Withdrawal can start within 12 hours, causing intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

Commonly encountered opioids and clinical features of poisoning are shown in Box 7.12. Needle tracks may be visible in intravenous users and there may be drug-related paraphernalia. Methadone may also cause QTc prolongation and torsades de pointes. Features of opioid poisoning can be prolonged for up to 48 hours after use of long-acting agents such as methadone or oxycodone.

Use of the specific opioid antagonist naloxone (0.4–2 mg IV in an adult, repeated if necessary) may obviate the need for intubation, although excessive doses may precipitate acute withdrawal in chronic opiate users and breakthrough pain in those receiving opioids for pain management. Repeated doses or an infusion are often required because the half-life of the antidote is short compared to that of most opiates, especially those with prolonged elimination. Patients should be monitored for at least 6 hours after the last naloxone dose. Rare complications of naloxone therapy include fits, ventricular arrhythmias and pulmonary oedema.
**Gamma hydroxybutyrate**

Gamma hydroxybutyrate (GHB), and the related compounds gamma butyrolactone (GBL) and 1,4 butanediol are sedative liquids with psychidelic and body-building effects.

As well as sedative hypnotic features (see Box 7.12), toxicity may cause nausea, diarrhoea, vertigo, tremor, myoclonus, extrapyramidal signs, euphoria, bradydyskinesia, convulsions, metabolic acidosis, hypokalaemia and hyperglycaemia. Coma usually resolves abruptly within a few hours but occasionally persists for several days. Dependence may develop in regular users, who experience severe, prolonged withdrawal effects if use is discontinued suddenly.

Management is largely supportive. All patients should be observed for a minimum of 2 hours and until symptoms resolve, with monitoring of blood pressure, heart rate, respiratory rate and oxygenation. Withdrawal symptoms may require treatment with very high doses of benzodiazepine.

---

**Stimulants and entactogens**

These are sympathomimetic and serotonergic amines that have overlapping clinical features, depending on the balance of their stimulant (see Box 7.12) and serotonergic (see Box 7.10) effects. As well as traditional drugs such as cocaine, amphetamines and ecstasy, the group includes many more recently emerging novel psychoactive substances, including cathinones (e.g. mephedrone), piperazines (e.g. benzylpiperazine), piperadines (e.g. ethylphenidate), benzofurans (e.g. 5-aminopropylbenzofuran) and NBOMe compounds (e.g. 25I-NBOMe).

**Cocaine**

Cocaine is available as a water-soluble hydrochloride salt powder suitable for nasal inhalation (‘snorting’), or as insoluble free-base (‘crack’ cocaine) ‘rocks’ that, unlike the hydrochloride salt, vapourise at high temperature and can be smoked, giving a more rapid and intense effect.

Effects appear rapidly after inhalation and especially after smoking. Sympathomimetic stimulant effects predominate (see Box 7.12). Serious complications usually occur within 3 hours of use and include coronary artery spasm, leading to myocardial ischaemia or infarction, hypotension and ventricular arrhythmias. Cocaine toxicity should be considered in younger adults presenting with ischaemic chest pain. Hyperpyrexia, rhabdomyolysis, acute renal failure and disseminated intravascular coagulation may occur.

A 12-lead ECG and ECG monitoring should be undertaken. ST segment elevation may occur in the absence of myocardial infarction and troponin T estimations are the most sensitive and specific markers of myocardial damage. Benzodiazepines and intravenous nitrates are useful for managing patients with chest pain or hypertension. Acidosis should be corrected and physical cooling measures used for hyperthermia. Beta-blockers may be contraindicated because of the risk of unopposed α-adrenoceptor stimulation, but this is debated. Coronary angiography should be considered in patients with myocardial infarction or acute coronary syndromes.

**Amphetamines and cathinones**

Amphetamine-related compounds include amphetamine sulphate (‘speed’), methylamphetamine (‘crystal meth’) and 3,4-methylenedioxymethamphetamine (MDMA, ‘ecstasy’). Synthetic cathinones include mephedrone and methylenedioxypyrovalerone. Tolerance is common, leading regular users to seek ever higher doses.

Toxic features usually appear within a few minutes of use and last 4–6 hours, or substantially longer after a large overdose. Sympathomimetic stimulant and serotonergic effects are common (see Boxes 7.10 and 7.12). Some users develop hyponatraemia as a result of excessive water-drinking or inappropriate vasopressin (antidiuretic hormone, ADH) secretion. Muscle rigidity, pain and bruxism (clenching of the jaw), hyperpyrexia, rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation, hepatocellular necrosis, acute respiratory distress syndrome (ARDS) and cardiovascular collapse have all been described following MDMA use. Cerebral infarction and haemorrhage have been reported, especially after intravenous amphetamine use.

Management is supportive and directed at complications (see Box 7.8).

---

**Hallucinogens**

**Cannabis**

Derived from the dried leaves and flowers of Cannabis sativa, cannabis produces euphoria, perceptual alterations and conjunctival injection, followed by enhanced appetite, relaxation and occasionally hypertension, tachycardia, slurred speech and ataxia. Effects occur 10–30 minutes after smoking or 1–3 hours after ingestion, and last 4–8 hours. High doses may produce anxiety, delirium, hallucinations and psychosis. Psychological dependence is common, but tolerance and withdrawal symptoms are unusual. Long-term use is thought to increase the lifetime risk of psychosis. Serious acute toxicity is uncommon and supportive treatment is all that is required.

**Synthetic cannabinoid receptor agonists**

Large numbers of synthetic cannabinoid receptor agonists (SCRAs), synthetic compounds sometimes referred to collectively as ‘spice’, are now used as legal alternatives to cannabis; examples include PB-22, 5F-PB-22, 5F-ADB, STS-135, SF-ADB and MDMB-CHMICA. They are usually sprayed on to a herbal smoking mix and packaged as smoking products with appealing brand names. These may contain more than one SCRA and content may change with time.

The toxic effects of SCRAs differ from those of cannabis, being generally more marked and including agitation, panic, delirium, hallucinations, tachycardia, ECG changes, hypotonia, dyspnoea and vomiting. Coma, respiratory acidosis, seizures, hypokalaemia and renal dysfunction are also reported. Treatment of intoxication is supportive.

**Tryptamines**

These are predominantly 5-hydroxytryptamine (5-HT, serotonin; especially 5-HT2A) agonists with associated stimulant effects. Typical clinical features include hallucinations, agitation, delirium, hypertension, tachycardia, sweating, anxiety and headache. Serotonin syndrome may occur (see Box 7.10), especially if tryptamines are used in combination with other serotonergic agents. Naturally occurring examples are psilocin and psilocybin, found in ‘magic mushrooms’, and dimethyltryptamine (DMT) in traditional ayahuasca brews. Synthetic tryptamines, such as alpha-methyltryptamine (AMT), have been encountered recently.
**d-Lysergic acid diethylamide**

*d*-Lysergic acid diethylamide (LSD) is a synthetic ergoline usually ingested as small squares of impregnated absorbent paper (often printed with a distinctive design) or as ‘microdots’. The drug causes perceptual effects, such as heightened visual awareness of colours or distortion of images. Hallucinations may be pleasurable or terrifying (‘bad trip’). Other features are delirium, agitation, aggression, dilated pupils, hypertension, pyrexia and metabolic acidosis. Psychosis may sometimes last several days.

Patients with psychotic reactions or CNS depression should be observed in hospital, preferably in a quiet, dimly lit room to minimise external stimulation. A benzodiazepine that can be used for sedation is required, avoiding antipsychotics if possible, as they may precipitate cardiovascular collapse or convulsions.

**Dissociative drugs**

Ketamine, its *N*-ethyl derivative methoxetamine and phencyclidine (now rarely encountered) produce a sense of dissociation from reality, often associated with visual and auditory distortions. Memory loss, impaired consciousness, agitation, hallucinations, tremors and numbness may also occur. Long-term ketamine (and probably methoxetamine) use can cause severe chronic cystitis with dysuria, frequency, urgency, haematuria and incontinence. Treatment of intoxication is supportive.

**Volatile substances**

Inhalation of volatile nitrites (e.g. amyl nitrite, isobutyl nitrite), often sold in bottles or vials as ‘poppers’, is reported to produce a feeling of pleasure and warmth, relax the anal sphincter and prolong orgasm. These potent vasodilators commonly provoke headache, dizziness, hypotension and tachycardia. They also oxidise haemoglobin to produce methaemoglobinaemia, with resulting breathlessness and delirium. Severe cases are treated with methylthioninium chloride (‘methylene blue’, see Fig 7.1).

Several volatile solvents found in household products, such as propane, butane, toluene and trichloroethylene, have a mild euphoriant effect if inhaled. Serious toxic effects can occur, including reduced level of consciousness, seizures and cardiac arrhythmias; there is also a risk of asphyxia from some methods of inhalation.

Nitrous oxide is an anaesthetic gas, but small canisters of it are sold for the domestic production of whipped cream and the contents of these can be transferred to balloons for inhalation. The gas has euphoriant effects (‘laughing gas’), but hazards include asphyxia from inhalation without oxygen, or vitamin B<sub>12</sub> inactivation from chronic use leading to megaloblastic anaemia, psychosis and other neurological sequelae.

**Body packers and body stuffers**

Body packers (‘mules’) attempt to smuggle illicit drugs (usually cocaine, heroin or amphetamines) by ingesting multiple small packages wrapped in several layers of clingfilm or in condoms. Body stuffers are those who have ingested unpackaged or poorly wrapped substances, often to avoid arrest. Both groups are at risk of severe toxicity if the packages rupture. This is more likely for body stuffers, who may develop symptoms of poisoning within 8 hours of ingestion. The risk of poisoning depends on the quality of the wrapping, and the amount and type of drug ingested. Cocaine, for example, presents a much higher risk than heroin because of its high toxicity and lack of a specific antidote.

Patients suspected of body packing or stuffing should be admitted for observation. A careful history taken in private is important, but for obvious reasons patients may withhold details of the drugs involved. The mouth, rectum and vagina should be examined as possible sites for concealed drugs. A urine toxicology screen performed at intervals may provide evidence of leakage, although positive results may reflect earlier drug use. Packages may be visible on plain abdominal films (Fig. 7.4) but ultrasound and computed tomography (CT) are more sensitive. One of these (preferably CT) should be performed in all suspected body packers.

Antimotility agents are often used by body packers to prevent premature passage of packages; it can take several days for packages to pass spontaneously, during which the carrier is at risk from package rupture. Whole bowel irrigation is commonly used to accelerate passage and is continued until all packages have passed. Surgery may be required when there is mechanical bowel obstruction or when evolving clinical features suggest package rupture, especially with cocaine.

**Chemicals and pesticides**

**Carbon monoxide**

Carbon monoxide (CO) is a colourless, odourless gas produced by faulty appliances burning organic fuels. It is also present in vehicle exhaust fumes and sometimes in smoke from house fires. It binds with haemoglobin and cytochrome oxidase, reducing tissue oxygen delivery and inhibiting cellular respiration. CO is a common cause of death by poisoning and most patients die before reaching hospital.

**Clinical features**

Early features include headache, nausea, irritability, weakness and tachypnoea. The cause of these non-specific features may not be obvious if the exposure is occult, such as from a...
faulty domestic appliance. Subsequently, ataxia, nystagmus, drowsiness and hyper-reflexia may develop, progressing to coma, convulsions, hypotension, respiratory depression, cardiovascular collapse and death. Myocardial ischaemia may result in arrhythmias or myocardial infarction. Cerebral oedema is common and rhabdomyolysis may cause myoglobinuria and renal failure. In those who recover from acute toxicity, longer-term neuropsychiatric effects are common, such as personality change, memory loss and concentration impairment. Extrapyramidal effects, urinary or faecal incontinence, and gait disturbance may also occur. Poisoning during pregnancy may cause fetal hypoxia and intrauterine death.

### Management

Patients should be removed from exposure as soon as possible and resuscitated as necessary. A high concentration of oxygen should be administered via a tightly fitting facemask; this reduces the half-life of carboxyhaemoglobin from 4–6 hours to about 40 minutes. Measurement of carboxyhaemoglobin is useful for confirming exposure; levels >20% suggest significant exposure but do not correlate well with the severity of poisoning, partly because concentrations fall rapidly after removal of the patient from exposure, especially if supplemental oxygen has been given.

An ECG should be performed in all patients with acute CO poisoning, especially those with pre-existing heart disease. Arterial blood gas analysis should be checked in those with serious poisoning. Pulse oximetry may provide misleading oxygen saturations because carboxyhaemoglobin and oxyhaemoglobin are both measured. Excessive intravenous fluid administration should be avoided, particularly in the elderly, because of the risk of pulmonary and cerebral oedema. Convulsions should be controlled with diazepam.

Hyperbaric oxygen therapy is controversial. At 2.5 atmospheres, this reduces the half-life of carboxyhaemoglobin to about 20 minutes and increases the amount of oxygen dissolved in plasma 10-fold, but systematic reviews have not consistently shown improved clinical outcomes. The logistical difficulties of transporting sick patients to hyperbaric chambers and managing them therein are substantial.

### Organophosphorus insecticides and nerve agents

Organophosphorus (OP) compounds (Box 7.13) are widely used as pesticides, especially in developing countries. Case fatality following deliberate ingestion is high (5–20%).

Nerve agents, developed for chemical warfare, are derived from OP insecticides and are much more toxic. They are commonly classified as G (originally synthesised in Germany) or V (‘venomous’) agents. The ‘G’ agents, such as tabun, sarin and soman, are volatile, absorbed by inhalation or via the skin, and dissipate rapidly after use. ‘V’ agents, such as VX, are contact poisons unless aerosolised, and contaminate ground for weeks or months.

The toxicology and management of nerve agent and pesticide poisoning are similar.

### Mechanism of toxicity

OP compounds inactivate acetylcholinesterase (AChE), resulting in the accumulation of acetylcholine (ACh) in cholinergic synapses (Fig. 7.5). Initially, spontaneous hydrolysis of the OP–enzyme complex allows reactivation of the enzyme but, subsequently, loss of a chemical group from the OP–enzyme complex prevents further enzyme reactivation. After this process (termed ‘ageing’) has taken place, new enzyme needs to be synthesised before function can be restored. The rate of ‘ageing’ is an important determinant of toxicity and is more rapid with dimethyl (3.7 hrs) than diethyl (31 hrs) compounds (Box 7.13) and especially rapid after exposure to nerve agents (soman in particular), which cause ‘ageing’ within minutes.

### Clinical features and management

OP poisoning causes an acute cholinergic phase, which may occasionally be followed by the intermediate syndrome or organophosphate-induced delayed polyneuropathy (OPIDN). The onset, severity and duration of poisoning depend on the route of exposure and agent involved.
Acute cholinergic syndrome

This usually starts within a few minutes of exposure and nicotinic or muscarinic features may be present (Box 7.14). Vomiting and profuse diarrhoea are typical following ingestion. Bronchoconstriction, bronchorrhoea and salivation may cause severe respiratory compromise. Excess sweating and miosis are characteristic and the presence of muscular fasciculations strongly suggests the diagnosis, although this feature is often absent, even in serious poisoning. Subsequently, generalised flaccid paralysis may develop and affect respiratory and ocular muscles, resulting in respiratory failure. Ataxia, coma, convulsions, cardiac repolarisation abnormalities and torsades de pointes may occur.

Management

The airway should be cleared of excessive secretions, breathing and circulation assessed, high-flow oxygen administered and intravenous access obtained. Appropriate external decontamination is needed (p. 133). Gastric lavage or activated charcoal may be considered if the patient presents sufficiently early. Seizures should be treated as described in Box 7.8. The ECG, oxygen saturation, blood gases, temperature, urea and electrolytes, amylase and glucose should be monitored closely.

Early use of sufficient doses of atropine is potentially life-saving in patients with severe toxicity. Atropine reverses ACh-induced bronchospasam, bronchorrhoea, bradycardia and hypotension. When the diagnosis is uncertain, a marked increase in heart rate associated with skin flushing after a 1 mg intravenous dose makes OP poisoning unlikely. In OP poisoning, atropine (2 mg IV) should be administered and this dose should be doubled every 5–10 minutes until clinical improvement occurs. Further bolus doses should be given until secretions are controlled, the skin is dry, blood pressure is adequate and heart rate is >80 bpm. Large doses may be needed, but excessive doses may cause anticholinergic effects (see Box 7.10).

In severe poisoning requiring atropine, an oxime such as pralidoxime chloride or obidoxime is generally recommended, if available, although efficacy is debated. This may reverse or prevent muscle weakness, convulsions or coma, especially if given rapidly after exposure. Oximes reactivate AChE that has not undergone ‘ageing’ and are therefore less effective with dimethyl compounds and nerve agents, especially soman. Oximes may provoke hypotension, especially if administered rapidly.

Intravenous magnesium sulphate has been reported to increase survival in animals and in small human studies of OP poisoning; however, further clinical trial evidence is needed before this can be recommended routinely.

Ventilatory support should be instituted before the patient develops respiratory failure. Benzodiazepines may be used to treat agitation, fasciculations and seizures and for sedation during mechanical ventilation.

Exposure is confirmed by measurement of plasma or red blood cell cholinesterase activity but antidote use should not be delayed pending results. Plasma cholinesterase is reduced more rapidly but is less specific than red cell cholinesterase. Values correlate poorly with the severity of clinical features but are usually <10% in severe poisoning, 20–50% in moderate poisoning and >50% in subclinical poisoning.

The acute cholinergic phase usually lasts 48–72 hours, with most patients requiring intensive cardiorespiratory support and monitoring. Cholinergic features may be prolonged over several weeks with some lipid-soluble agents.

Intermediate syndrome

About 20% of patients with OP poisoning develop weakness that spreads rapidly from the ocular muscles to those of the head and neck, proximal limbs and the muscles of respiration, resulting in ventilatory failure. This ‘intermediate syndrome’ generally develops 1–4 days after exposure, often after resolution of the acute cholinergic syndrome, and may last 2–3 weeks. There is no specific treatment and supportive care is needed, including maintenance of airway and ventilation.

Organophosphate-induced delayed polyneuropathy

Organophosphate-induced delayed polyneuropathy (OPIDN) is a rare complication that usually occurs 2–3 weeks after acute exposure. It is a mixed sensory/motor polyneuropathy, affecting long myelinated neurons especially, and appears to result from inhibition of enzymes other than AChE. It is a feature of poisoning with some OPs such as triorthocresyl phosphate but is less common with nerve agents. Early clinical features are muscle cramps followed by numbness and paraesthesia, proceeding to flaccid paralysis of the lower and subsequently the upper limbs, with foot and wrist drop and a high-stepping gait, progressing to paraplegia. Sensory loss may also be present but is variable. Initially, tendon reflexes are reduced or lost but mild spasticity may develop later.

There is no specific therapy for OPIDN. Regular physiotherapy may limit deformity caused by muscle-wasting. Recovery is often incomplete and may be limited to the hands and feet, although substantial functional recovery after 1–2 years may occur, especially in younger patients.

Carbamate insecticides

Carbamate insecticides such as bendiocarb, carbofuran, carbaryl and methomyl inhibit a number of tissue esterases, including AChE. The mechanism, clinical features and management of toxicity are similar to those of OP compounds. However, clinical features are usually less severe and of shorter duration, because the carbamate–AChE complex dissociates quickly, with a half-life of 30–40 minutes, and does not undergo ageing. Also, carbamates penetrate the CNS poorly. Intermediate syndrome...
and OPIDN are not common features of carbamate poisoning. In spite of this, case fatality can be high for some carbamates, depending on their formulation.

Atropine may be given intravenously as for OP poisoning (p. 146). Diazepam may be used to relieve anxiety. The use of oximes is unnecessary.

**Paraquat**

Paraquat is a herbicide that is widely used across the world, although it has been banned in the European Union and some other countries for several years. It is highly toxic if ingested, with clinical features including oral burns, vomiting and diarrhoea, progressing to pneumonitis, pulmonary fibrosis and multi-organ failure.

Exposure can be confirmed by a urinary dithionite test, while the plasma paraquat concentration indicates prognosis. There is no specific antidote but activated charcoal is commonly administered. Immunosuppression with glucocorticoids and cyclophosphamide is sometimes used but evidence for benefit is weak. Irrespective of treatment, death is common and may occur within 24 hours with substantial poisoning or after 1–2 weeks with lower doses.

**Chemicals and pesticides**

Paraquat is a herbicide that is widely used across the world, although it has been banned in the European Union and some other countries for several years. It is highly toxic if ingested, with clinical features including oral burns, vomiting and diarrhoea, progressing to pneumonitis, pulmonary fibrosis and multi-organ failure.

Exposure can be confirmed by a urinary dithionite test, while the plasma paraquat concentration indicates prognosis. There is no specific antidote but activated charcoal is commonly administered. Immunosuppression with glucocorticoids and cyclophosphamide is sometimes used but evidence for benefit is weak. Irrespective of treatment, death is common and may occur within 24 hours with substantial poisoning or after 1–2 weeks with lower doses.

### Methanol and ethylene glycol

Ethylene glycol (1,2-ethanediol) is found in antifreeze, brake fluids and, in lower concentrations, windscreen washes. Methanol is present in some antifreeze products and commercially available industrial solvents, and in low concentrations in some screen washes and methylated spirits. It may also be an adulterant of illicitly produced alcohol. Both are rapidly absorbed after ingestion.

Methanol and ethylene glycol are not of high intrinsic toxicity but are converted via alcohol dehydrogenase to toxic metabolites that are largely responsible for their clinical effects (Fig. 7.6).

**Clinical features**

Early features of poisoning with either methanol or ethylene glycol include vomiting, ataxia, drowsiness, dysarthria and nystagmus. As toxic metabolites are formed, metabolic acidosis, tachypnoea, coma and seizures may develop.

Toxic effects of ethylene glycol include ophthalmoplegia, cranial nerve palsies, hyporeflexia and myoclonus. Renal pain and acute tubular necrosis occur because of renal calcium oxalate precipitation. Hypocalcaemia, hypomagnesaemia and hyperkalaemia are common.

Methanol poisoning causes headache, delirium and vertigo. Visual impairment and photophobia develop, associated with optic disc and retinal oedema and impaired pupil reflexes. Blindness may be permanent, although some recovery may occur over several months. Pancreatitis and abnormal liver function have also been reported.

**Management**

Urea and electrolytes, chloride, bicarbonate, glucose, calcium, magnesium, albumin, plasma osmolarity and arterial blood gases should be measured in all patients with suspected methanol or ethylene glycol toxicity. The osmolar and anion gaps should be calculated (see Box 7.5). Initially, poisoning is associated with an increased osmolar gap, but as toxic metabolites are produced, an increased anion gap develops, associated with metabolic acidosis. The diagnosis can be confirmed by measurement of ethylene glycol or methanol concentrations but assays are not widely available.

An antidote, ideally fomepizole but otherwise ethanol, should be administered to all patients with suspected significant exposure while awaiting the results of laboratory investigations. These block alcohol dehydrogenase and delay the formation of toxic metabolites until the parent drug is eliminated in the urine or by dialysis. The antidote should be continued until ethylene glycol or methanol concentrations are undetectable. Metabolic acidosis should be corrected with sodium bicarbonate (e.g. 250 mL of 1.26% solution, repeated as necessary). Convulsions should be treated with an intravenous benzodiazepine. In ethylene glycol poisoning, hypocalcaemia should be corrected only if there are severe ECG features or if seizures occur, as this may increase calcium oxalate crystal formation. In methanol poisoning, folic acid should be administered to enhance the metabolism of the toxic metabolite, formic acid.

Haemodialysis or haemodiafiltration should be used in severe poisoning, especially if renal failure is present or there is visual loss in the context of methanol poisoning. It should be continued until acute toxic features are no longer present and ethylene glycol/methanol concentrations are undetectable.

**Corrosive substances**

Products containing strong acids (e.g. hydrochloric or sulphuric acid) or alkalis (e.g. sodium hydroxide, calcium carbonate) may be ingested, accidentally or intentionally, causing gastrointestinal pain, ulceration and necrosis, with risk of perforation.

External decontamination (p. 133), if needed, should be performed after initial resuscitation. Gastric lavage should not be attempted and neutralising chemicals should not be administered after large ingestions because of the risk of tissue damage from heat release. Cardiorespiratory monitoring is necessary and full blood count, renal function, coagulation and acid–base status should be assessed. An erect chest X-ray should be performed if perforation is suspected and may show features of mediastinitis or gas under the diaphragm. Strong analgesics should be administered for pain.

Severe abdominal or chest pain, abdominal distension, shock or acidosis may indicate perforation and should prompt an urgent CT scan of chest and abdomen and surgical review. In the absence of perforation, drooling, dysphagia, stridor or oropharyngeal burns suggest possible severe oesophageal
damage and early endoscopy by an experienced operator should be considered. Delayed endoscopy (e.g. after several days) may carry a higher risk of perforation.

Aluminium and zinc phosphide

These rodenticides and fumigants are a common means of self-poisoning in northern India. The mortality rate for aluminium phosphide ingestion has been estimated at 60%; zinc phosphide ingestion appears less toxic, at about 2%. When ingested, both compounds react with gastric acid to form phosphine, a potent pulmonary and gastrointestinal toxicant. Clinical features include severe gastrointestinal disturbances, chest tightness, cough and breathlessness progressing to ARDS and respiratory failure, tremor, paraesthesiae, convulsions, coma, tachycardia, metabolic acidosis, electrolyte disturbances, hypoglycaemia, myocarditis, liver and renal failure, and leucopenia. Ingestion of a few tablets can be fatal.

Treatment is supportive and directed at correcting electrolyte abnormalities and treating complications; there is no specific antidote. Early gastric lavage is sometimes used, often with vegetable oil to reduce the release of toxic phosphine, but the benefit is uncertain.

Copper sulphate

This is used as a fungicide. If it is ingested, clinical features of toxicity include nausea, vomiting, abdominal pain, diarrhoea, discoloured (blue/green) secretions, corrosive effects on the gastrointestinal tract, renal or liver failure, methaemoglobinaemia, haemolysis, rhabdomyolysis, convulsions and coma. Treatment is as for other corrosive substances (see above) and should address complications, including use of methylthioninium chloride for methaemoglobinaemia (see Fig. 7.1). Chelation therapy is unlikely to be beneficial after acute exposure.

Chemicals less commonly taken in poisoning

An overview of the clinical features and management for chemicals less commonly involved in poisoning is provided in Box 7.15.

(DMSA = dimercaptosuccinic acid)
Chemical warfare agents

Some toxins have been developed for use as chemical warfare agents. These are summarised in Box 7.16.

Environmental poisoning

Arsenism

Chronic arsenic exposure from drinking water has been reported in many countries, especially India, Bangladesh, Nepal, Thailand, Taiwan, China, Mexico and South America, where a large proportion of the drinking water (ground water) has a high arsenic content, placing large populations at risk. The World Health Organisation (WHO) guideline value for arsenic content in tube well water is 10 μg/L.

Health effects associated with chronic exposure to arsenic in drinking water are shown in Box 7.17. In exposed individuals, high concentrations of arsenic are present in bone, hair and nails. Specific treatments are of no benefit in chronic arsenic toxicity and recovery from the peripheral neuropathy may never be complete, so the emphasis should be on prevention.

Fluorosis

Fluoride poisoning can result from exposure to excessive quantities of fluoride (>10 ppm) in drinking water, industrial exposure to fluoride dust or consumption of brick teas. Clinical features include yellow staining and pitting of permanent teeth, osteosclerosis, soft tissue calcification, deformities (e.g. kyphosis) and joint ankylosis. Changes in the bones of the thoracic cage may lead to rigidity that causes dyspnoea on exertion. Very high doses of fluoride may cause abdominal pain, nausea, vomiting, seizures and muscle spasm. In calcium-deficient children, the toxic effects of fluoride manifest even at marginally high exposures to fluoride.

In endemic areas, such as Jordan, Turkey, Chile, India, Bangladesh, China and Tibet, fluorosis is a major public health problem, especially in communities engaged in physically strenuous agricultural or industrial activities. Dental fluorosis is endemic in East Africa and some West African countries.

Food-related poisoning

Paralytic shellfish poisoning

Paralytic shellfish poisoning is caused by consumption of bivalve molluscs (e.g. mussels, clams, oysters, cockles and scallops) contaminated with saxitoxins, which are concentrated in the shellfish as a result of constant filtration of toxic algae during algal blooms (e.g. ‘red tide’). Symptoms develop within 10–120 minutes of eating the contaminated shellfish and include gastrointestinal disturbances, paraesthesia around the mouth or in the extremities, ataxia, mental state changes and dysphagia. In severe cases, paralysis and respiratory failure can develop. There is no specific antidote and treatment is supportive. Most cases resolve over a few days.

Ciguatera poisoning

Ciguatera toxin and related toxins are produced by dinoflagellate plankton that adhere to algae and seaweed. These accumulate in the tropical herbivorous fish that feed on these and in their larger predators (e.g. snapper, barracuda), especially in the
Pacific and Caribbean. Human exposure occurs through eating contaminated fish, even if well cooked. Nausea, vomiting, diarrhoea and abdominal pain develop within a few hours, followed by paraesthesia, ataxia, blurred vision, ataxia and tremor. Convulsions and coma can occur, although death is uncommon. Fatigue and peripheral neuropathy can be long-term effects. There is no specific treatment. In the South Pacific and Caribbean, there are approximately 50,000 cases per year, with a case fatality of 0.1%.

Scombrototoxic fish poisoning

Under poor storage conditions, histidine in scombroid fish (e.g. tuna, mackerel, bonito, skipjack and the canned dark meat of sardines) may be converted by bacteria to histamine and other chemicals. Within minutes of consumption, flushing, burning, sweating, urticaria, pruritus, headache, colic, nausea and vomiting, diarrhoea, bronchospasm and hypotension may occur. Management is with nebulised salbutamol, intravenous antihistamines and, occasionally, intravenous fluid replacement.

Plant poisoning

A substantial number of plants and fungi are potentially toxic if consumed, with patterns of poisoning depending on their geographical distribution. Some toxic examples and the clinical features of toxicity are shown in Box 7.18.

Comprehensive evaluation of the envenomed patient

1. **Airway, breathing, circulation**
   - Blood pressure
   - Pulse
   - Respiration rate
   - Oxygen saturation
   - Dysrhythmias

2. **Level of consciousness**
   - Confusion
   - Agitation
   - Seizures

3. **Mouth, gums**
   - Evidence of bleeding
   - Increased salivation
   - Drooling

4. **Cranial nerves**
   - Drooling
   - Dysarthria
   - Dysphagia
   - Upper airway compromise

5. **Chest**
   - Pulmonary oedema
   - Diminished respiration

6. **Bite/sting site**
   - Pain
   - Swelling
   - Bruising
   - Discoloration
   - Necrosis

7. **Reflexes**
   - Decreased or absent reflexes

8. **Muscles**
   - Weakness
   - Tenderness
   - Pain

9. **Lymph nodes**
   - Tender or enlarged nodes draining bite/sting area

10. **Abdomen**
    - Intra-abdominal, retroperitoneal or renal pathology

11. **Skin**
    - In addition to (6):
      - Piloerection
      - Erythema
      - Blistering
      - Infection

12. **Eyes**
    - Miosis or mydriasis
    - Increased lacrimation
    - Corneal injury (venom spit injury)

Additional observations:

- **Bilateral mild ptosis**
- **Ptosis and lateral ophthalmoplegia**
- **Fixed dilated pupils**
- **Chemosis – can indicate capillary leak syndrome**
- **Local increased sweating**
- **Local bleeding, blistering**
- **Local bleeding**

Geographical distribution of venomous snakes

The geographical location of a snakebite determines the likely animal(s) involved and the nature and risks of the envenomation.

Bedside tests in the envenomed patient

Examination of urine. Haematuria may indicate a coagulopathy. Dark urine is suggestive of myoglobinuria, which is a sign of extensive rhabdomyolysis. Copyright © Julian White.

Twenty-minute whole-blood clotting test (20WBCT). The presence of coagulopathy is a key indicator of major envenoming for some species. While full laboratory coagulation studies may be the ideal, the 20WBCT has emerged as a simple standardised bedside test of coagulopathy, applicable even in areas with limited health facilities. Copyright © Julian White.
Overview of envenomation

Envenomation occurs when a venomous animal injects sufficient venom by a bite or a sting into a prey item or perceived predator to cause deleterious local and/or systemic effects. This is defined as a venom-induced disease (VID). Venomous animals generally use their venom to acquire and, in some cases, pre-digest prey, with defensive use a secondary function for many species. Accidental encounters between venomous animals and humans are frequent, particularly in the rural tropics, where millions of cases of venomous bites and stings occur annually. Globally, an increasing number of exotic venomous animals are kept privately, so cases of envenoming may present to hospitals where doctors have insufficient knowledge to manage potentially complex presentations. Doctors everywhere should thus be aware of the basic principles of management of envenomation and how to seek expert support. It is important for doctors to know what types of venomous animal are likely to occur in their geographical area (hospital hinterland; p. 153) and the types of envenoming they may cause.

Venom

Venom is a complex mixture of diverse components (notably toxins), often with several separate toxins that can cause adverse effects in humans, and each is potentially capable of multiple effects (Box 8.1). Venom is produced at considerable metabolic cost, so is used sparingly; thus only some bites/stings by venomous animals result in significant envenoming, the remainder being ‘dry bites’. The concept of dry bites is important in understanding approaches to first aid and medical management.

Venomous animals

There are many animal groups that contain venomous species (Box 8.2). The epidemiological estimates reflect the importance of snakes and scorpions as causes of severe or lethal envenomation, but also the fragmentary nature of the data. For snakes, recent studies have proposed widely varying estimates of epidemiological impact, but even the higher estimates may be too low. A recent

comprehensive study in India indicated there are at least 45 000 snakebite-related deaths in that country annually, far above both government figures and previous estimates. In many areas of the poor rural tropics, health resources are limited and few envenomings are either seen or recorded within the official hospital system, compared to the actual community burden of disease. While fatal cases may gain most attention, long-term disability from envenomation affects significantly more people and has a major social and economic cost.

Stings by social insects such as bees and wasps may also cause lethal anaphylaxis. Other venomous animals may commonly envenom humans but cause mostly non-lethal effects. A few animals only rarely envenom humans but have a high potential for severe or lethal envenoming. These include box jellyfish, cone snails, blue-ringed octopus, paralysis ticks and Australian funnel web spiders. Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are funnel web spiders. Within any given group, particularly snakes, there may be a wide range of clinical presentations. Some are described here but for a more detailed discussion of the types of venomous animal, their venoms and their effects on humans, see toxinology.com.

### Clinical effects

With the exception of dry bites, where no significant toxin effects occur, venomous bites/stings can result in three broad classes of effect.

### Local effects

These vary from trivial to severe (Box 8.3). There may be minimal or no local effects with some snakebites (not even pain), yet lethal systemic envenoming may still be present. For other species, local effects predominate over systemic, and for some, such as certain snakes, both are important (p. 152). Some species commonly cause local necrosis, notably some snakes, brown recluse spiders, an Iranian scorpion (*Hemiscorpius lepturus*) and some stingrays.

### Specific systemic effects

These are important in both diagnosis and treatment.

- **Neurotoxic flaccid paralysis** can develop very rapidly, progressing from mild weakness to full respiratory paralysis in less than 30 minutes (blue-ringed octopus bite, cone snail sting), or may develop far more slowly, over hours (some snakes) to days (paralysis tick). For neurotoxic snakes, the cranial nerves are usually involved first, with ptosis a common initial sign, often progressing to partial and later complete ophthalmoplegia, fixed dilated pupils, drooling and loss of upper airway protection (p. 152). From this, paralysis may extend to the limbs, with weakness and loss of deep tendon reflexes, the neck (‘broken neck’ sign), then finally respiratory paralysis affecting the diaphragm.

- **Excitatory neurotoxins** cause an ‘autonomic storm’, often with profuse sweating (p. 152), variable cardiac effects and cardiac failure, sometimes with pulmonary oedema (notably, Australian funnel web spider bite, some scorpions such as Indian red scorpion). This type of envenomation can be rapidly fatal (many scorpions, funnel web spiders), or may cause distressing symptoms but constitute a lesser risk of death (widow spiders, banana spiders).

- **Myotoxicity** can be localised in the bitten limb, or systemic, affecting mostly skeletal muscles. It can initially be silent, then present with generalised muscle pain, tenderness, myoglobinuria (p. 153) and huge rises in serum creatine kinase (CK). Secondary renal failure can precipitate potentially lethal hyperkalaemic cardiotoxicity.

- **Cardiotoxicity** is often secondary but symptoms and signs are non-specific in most cases. For some scorpions, envenomation can cause direct cardiac effects, including decreased cardiac output, arrhythmias and pulmonary oedema.

- **Haemostasis system toxins** cause a variety of effects, depending on the type of toxin (Fig. 8.1). Coagulopathy may present as bruising and bleeding from the bite site (p. 152), gums and intravenous sites. Surgical interventions are high-risk in such cases. Other venoms cause thrombosis, usually presenting as deep venous thrombosis (DVT), pulmonary embolus or stroke (particularly Caribbean/Martinique vipers).

- **Haemorrhagic toxins** cause vascular damage, especially in the bitten limb, with extravasation of fluid and sometimes hypotensive shock; this is a problem associated with some snakebites. The role of these toxins in causing late-developing capillary leak syndrome (p. 152), again
First aid can be crucial in determining the outcome for envenomed patients, yet throughout much of the world inappropriate and dangerous first aid is often administered.

Renal damage in envenoming is mostly secondary, although some species, such as Russell’s vipers, can cause primary renal damage. The presentation is similar in both cases, with changes in urine output (polyuria, oliguria or anuria) or rises in creatinine and urea. In cases with intravascular haemolysis, secondary renal damage is likely. The clinical effects of specific animals in different regions of the world are shown in Boxes 8.4–8.6.

**General approach to the envenomed patient**

First aid

First aid can be crucial in determining the outcome for envenomed patients, yet throughout much of the world inappropriate and dangerous first aid is often administered.

A significant proportion of venom is transported from the bite/sting site via the lymphatic system, particularly for venoms with larger molecular weight toxins, such as many snake venoms. It is recommended that for most forms of envenoming, the patient should be kept still, the bitten limb immobilised with a splint and vital systems supported, where required. A patent upper airway should be specifically ensured and respiratory support provided, if required. For some animals, notably snakes in certain regions, the use of a local pressure pad bandage over the bite site (Myanmar) or a pressure immobilisation bandage (Australia, New Guinea) is recommended.

Ineffective or dangerous first aid, such as suction devices, ‘cut and suck’, local chemicals, snake stones (stones of some sort placed over the snakebite) and tourniquets, should not be used. Tourniquets, in particular, have the potential to cause catastrophic distal limb injuries in snakebite when applied too narrowly or too tightly, or left on too long.

### Transporting patients

Where possible, transport should be brought to the patient. It is also vital to obtain medical assessment and intervention at the earliest opportunity, however, so any delay in transporting the patient to a medical facility should be avoided. Severely envenomed patients may develop life-threatening problems, such as shock or respiratory failure, during transport, so ideally the transport method used should allow for management of these problems en route.

In resource-poor environments, simple solutions for rapid transport have been successfully employed, such as motorbikes or similar with the patient supported between the driver in front and another person behind the patient. However, this method cannot cope with a patient developing airway compromise or respiratory failure, such as from developing neurotoxicity.
dilated pupils, absent reflexes, no withdrawal response to painful stimuli, no movement of limbs, fixed forward gaze with gross ptosis; p. 152) when, in fact, the patient is conscious.

Assessment for evidence of envenoming

As in other areas of medicine, comprehensive assessment of a patient bitten/stung by a venomous animal requires a good history, a careful targeted examination and, where appropriate, ‘laboratory’ testing (though the latter may just consist of simple bedside tests performed by the doctor; p. 153). Animals that are unlikely to cause serious envenomation in humans should be identified so that inappropriate admission and intervention are avoided. Occasionally, patients may be unaware they have been bitten/stung and thus provide a misleading history. In regions of the world where keeping or handling venomous animals is illegal, patients may be reticent in giving a truthful history. Multiple bites or stings are more likely to cause major envenoming.

The following key questions should be asked:

• When was the patient exposed to the venomous bite/sting?
• Was the organism causing it seen and what did it look like (size, colour)?
• What were the circumstances (on land, in water etc.)?
• Was there more than one bite/sting?
• What first aid was used, when and for how long?
• What symptoms has the patient had (local and systemic)?
• Are there symptoms suggesting systemic envenoming (paralysis, rhabdomyolysis, coagulopathy etc.)?

Assessment and management in hospital

On arrival at a health station or hospital, there are two immediate priorities:

• identifying and treating any life-threatening problems (e.g. circulatory shock, respiratory failure; see Ch. 16)
• determining whether envenoming is present and if that requires urgent treatment.

Assessment and management of life-threatening problems

Patients who are seriously envenomed must be identified early so that appropriate management is not delayed. Critically ill patients must be resuscitated (p. 202) and this takes precedence over administration of any antivenom. Clinicians should look for signs of:

• shock/hypotension
• airway and/or respiratory compromise (likely to be secondary to flaccid paralysis)
• major bleeding, including internal bleeding (especially intracranial)
• impending limb compromise from inappropriate first aid (e.g. a tourniquet) – though beware sudden envenoming on removal of a tourniquet.

In a patient with severe neurotoxic flaccid paralysis, who is still able to maintain sufficient respiratory function for survival, clinical assessment may suggest irretrievable brain injury (fixed dilated pupils, absent reflexes, no withdrawal response to painful stimuli, no movement of limbs, fixed forward gaze with gross ptosis; p. 152) when, in fact, the patient is conscious.

• Is there any significant past medical history and medication use?
• Is there a past exposure to antivenom/venom and allergies?

If patients state that they have been bitten by a particular species, ensure this information is accurate. Private keepers of venomous animals may not have accurate knowledge of what they are keeping, and misidentification of a snake, scorpion or spider can have dire consequences if the wrong antivenom is used.

An outline of some principal findings on examination of the envenomed patient is shown on page 152. The patient may have a cluster of clinical features suggestive of a particular type of envenomation (see Box 8.1).

Even with dangerously venomous animals, some bites/stings will be dry bites and will not require antivenom. The time to onset of first symptoms and signs of envenomation is variable, depending on both animal and patient factors. It may range from a matter of minutes post-bite/sting to 24 hours later in some cases. Therefore, the initial assessment, if normal, must be repeated multiple times during the first 24 hours. Some types of envenomation will not cause symptoms or signs at all, or they may appear very late, long after the optimum time for treatment has passed. Evidence of envenomation may become apparent only through laboratory testing.

### Laboratory investigations

Specific tests for venom are currently commercially available only for Australian snakebites but are likely to be developed for snakebites in other regions. They are not available for other types of envenomation, where venom concentrations are low. For snakebite, a screen for envenoming includes full blood count, coagulation screen, urea and electrolytes, creatinine, CK and electrocardiogram (ECG). Lung function tests, peripheral oximetry or arterial blood gases may be indicated in cases with potential or established respiratory failure. In areas without access to routine laboratory tests, the 20-minute whole-blood clotting test (20WBCT) is useful (p. 153).

### Treatment

Once a diagnosis of likely envenoming has been made, the next urgent decision is whether to give antivenom. Antivenom may not be the only crucial treatment, however. For a snakebite by a potentially lethal species such as Russell’s viper, the patient might have local effects with oedema, blistering, necrosis, and resultant fluid shifts causing shock, and at the same time have systemic effects such as intractable vomiting, coagulopathy, paralysis and secondary renal failure. Specific treatment with antivenom will be required to reverse the coagulopathy and may prevent worsening of the paralysis and reduce the vomiting, but will not greatly affect the local tissue damage or the renal failure or shock. The latter will require intravenous fluid therapy, possibly respiratory support, renal dialysis and local wound care, perhaps including antibiotics.

Each venomous animal will cause a particular pattern of envenomation, requiring a tailored response. Listing all of these is beyond the scope of this chapter (see ‘Further information’ below).

### Antivenom

Antivenom, sometimes inappropriately labelled as ‘anti-snake venom’ (ASV), is the most important tool in treating envenomation. It is made by hyperimmunising an animal, usually horses, to produce antibodies against venom. Once refined, these bind to venom toxins and render them inactive or allow their rapid clearance. Antivenom is available only for certain venomous animals and cannot reverse all types of envenomation. With a few exceptions, it should be given intravenously, with adrenaline (epinephrine) ready in case of anaphylaxis. It should be used only when clearly indicated, and indications will vary between venomous animals (Box 8.7). It is critical that the correct antivenom is used at the appropriate dose. Doses vary widely between antivenoms. In some situations (such as the Indian subcontinent), pre-treatment with subcutaneous adrenaline may reduce the chance of anaphylaxis to antivenom.

Antivenom can sometimes reverse post-synaptic neurotoxic paralysis (α-bungarotoxin-like neurotoxins) but will not usually reverse established pre-synaptic paralysis (β-bungarotoxin-like neurotoxins), so should be given before major paralysis has occurred (Fig. 8.2). Coagulopathy is best reversed by antivenom, but even after all venom is neutralised, there may be a delay of hours before normal coagulation is restored. More antivenom should not be given because coagulopathy has failed to normalise fully in the first 1–3 hours (except in very particular circumstances). Thrombocytopenia may persist for days, despite antivenom. The role of antivenom in reversing established rhabdomyolysis and renal failure is uncertain. Antivenom may help limit local tissue effects or injury in the bitten limb but this is quite variable and time-dependent. Neuroexcitatory envenomings can respond very well to antivenom (Australian funnel web spider bites and Mexican, South American and Indian scorpion stings) but there is controversy about the effectiveness of antivenom for some species (some North African and Middle Eastern scorpions). The role of antivenom in limiting local venom effects, including necrosis, is also controversial; it is most likely to be effective when given early.

All patients receiving antivenom are at risk of both early and late adverse reactions, including anaphylaxis (early; not always related to immunoglobulin E (IgE)) and serum sickness (late).

### Non-antivenom treatments

Anticholinesterases are used as an adjunctive treatment for post-synaptic paralysis.

Prazosin (an α-adrenoceptor antagonist) is used in the management of hypertension or pulmonary oedema in scorpion sting cardiotoxicity, particularly for Indian red scorpion stings, though antivenom is now the preferred treatment.
Abscess. Tetanus is a risk in some types of bite or sting, such as from venomous snakes. Envenomation by specific animals

Venomous snakes represent the single most important cause of envenomation globally, affecting millions of humans annually and resulting in large numbers of deaths and patients left with long-term disability. Of the 3000-plus snake species, more than 1000 are venomous or produce oral toxins. The most important venomous snake families are the Viperidae (vipers; includes typical vipers (subfamily Viperinae) and pit-vipers, with heat-sensing pit organs (subfamily Crotalinae)) and the Elapidae (cobras, kraits, mambas, coral snakes, sea snakes, Australian snakes). However, there are also dangerous species among the Atractaspidae (side-fanged burrowing vipers of Africa and the Middle East) and the non-front-fanged colubrids (NFFC snakes; several families, including the ‘back-fanged’ boomslang and vine snakes of Africa and the keelbacks of Asia).

A selection of important species is included in Boxes 8.4–8.6.

Clinical features and management

As with other forms of envenoming, the management of snakebite follows the standard assessment guidelines described previously (p. 152). The nature of the risks posed will depend on the specific snake fauna in a given region (p. 153). For example, in the Indian subcontinent, the major snakebite risks are claimed to come from the ‘big four’: cobras, kraits, Russell’s viper and saw-scaled vipers. This list is misleading, though, as it omits other important snakes, including the hump-nosed vipers, king cobra and green pit vipers, all of which can cause severe or lethal envenoming and may not be covered by current Indian antivenoms. Even for those snakes recognised as causing envenoming, there may be major geographical variation in venom and features of envenoming. For Russell’s viper (Daboia spp.), Sri Lankan specimens can cause rhabdomyolysis and flaccid paralysis, in addition to classic severe coagulopathy, haemorrhage, local bite site injury and acute kidney injury (AKI). Indian populations of the same snake are not associated with either rhabdomyolysis or paralysis, but in parts of Southern India may cause anterior pituitary haemorrhage and/or capillary leak syndrome (hypotensive shock plus vascular leakage resulting in pulmonary oedema). Capillary leak syndrome is also encountered with populations of Burmese Russell’s viper (Myanmar), where AKI is especially common and severe.

Antivenom raised against venom from one population of these snakes is often poorly effective against bites from snakes from other regions. Similarly, each of the several species of saw-scaled vipers (Echis spp.) spread from West Africa across the Middle East to the Indian subcontinent, including Sri Lanka, has specific venoms that may not be neutralised by antivenoms raised against other species in the genus; Indian antivenoms are ineffective against African species. It follows that, in managing snakebite envenomation, it is critically important to choose the appropriate antivenom and to understand that...

Follow-up

Cases with significant envenomation and those receiving antivenom should be followed up to ensure any complications have resolved and to identify any delayed envenoming.

Antibiotics are not routinely required for most bites/stings, though a few animals, such as some South American pit vipers and stingrays, regularly cause significant wound infection or abscess. Tetanus is a risk in some types of bite or sting, such as snakebite, but intramuscular toxoid should not be given until any coagulopathy is reversed.

Mechanical ventilation (p. 202) is vital for established respiratory paralysis that will not reverse with antivenom and may be required for prolonged periods (up to several months in some cases).

Fasciotomy as a treatment for potential compartment syndrome or severe limb swelling is an overused and often disastrous surgical intervention in snakebite and is associated with poor functional outcomes. It should be reserved as a treatment of last resort and be used only in cases where compartment syndrome is confirmed by intracompartment pressure measurement and after first trying limb elevation and antivenom, and ensuring that any coagulopathy has resolved.

Copyright © Julian White.
this may not include every antivenom claiming to cover a given species.

It is unwise to assume that everything is known about envenoming by snakes because new clinical information and syndromes are emerging as more detailed studies are carried out. For instance, krait bites (Bungarus spp.), long associated with ‘painless’ bites, later development of devastating flaccid paralysis and a high mortality rate, are now known to have some venom diversity. At least some species can cause rhabdomyolysis and/or severe hypotension, and while bites may be painless, systemic envenoming can cause severe abdominal pain in at least some patients. Among cobra bites, the previous division into ‘non-spitting’, neurotoxic species and ‘spitting’, less neurotoxic species that cause local necrosis is less clear. Non-spitters are now known to spit in parts of their range (e.g. Naja kaouthia in West Bengal) and may cause local necrosis in addition to paralysis. Previously clear diagnostic indicators for envenomation by particular types of snakes, such as Russel’s vipers and saw-scaled vipers causing coagulopathy, have also become less sure, as it is now known that other snakes, such as hump-nosed vipers (Hypanale spp.) and green pit vipers (Trimeresurus spp.), found in similar regions, can also cause marked coagulopathy and yet are often not covered by available antivenoms. The ability to cause life-threatening coagulopathy, associated with snakes previously considered harmless, such as the keelbacks in Asia (Rhabdophis spp.), can further complicate the diagnostic and management process, as antivenom against these snakes is currently available only in Japan.

### Scorpions

Scorpions are second only to snakes in their venomous impact on humankind. Most medically important scorpions are in the family Buthidae and have complex neuroexcitatory venoms with highly specific ion-channel toxins. Classically, stings by these scorpions (some key genera listed in Boxes 8.4–8.6) cause moderate to severe local pain and rapid-onset systemic envenoming with development of a catecholamine storm-like syndrome as the toxins target the nervous system. There may be tachycardia or bradycardia, hyper- or hypotension, profuse sweating, salivation, cardiac dysfunction and pulmonary oedema. Cardiac collapse can occur, especially in children. Other clinical features may vary, depending on the scorpion species.

The Iranian scorpion, *Hemiscorpius lepturus* (principally south-west Iran), causes a quite different presentation, with an initial minor sting, followed by progressive development of bite site or limb necrosis and a potentially lethal systemic envenoming, characterised by intravascular haemolysis, disseminated intravascular coagulation (DIC), secondary renal failure and shock.

**Clinical features and management**

The approach to management varies with species and region. In Latin America, specific antivenoms are routinely used and associated with improved outcomes and dramatic falls in mortality rate. In India, the past reliance on prazosin has been replaced with use of specific antivenom, again with improved outcomes. In contrast, in parts of North Africa, past reliance on antivenom has been replaced with use of cardiac support and arguably poorer outcomes.

In Iran, *H. lepturus* stings are treated with antivenom, though as presentation is often delayed because the sting initially appears to be minor, the role of late antivenom is unclear.

### Spiders

There are vast numbers and great species diversity of spiders, with two broad taxonomic groupings: the more ‘primitive’ Mygalomorphs (several medically important species, especially Australian funnel web spiders, *Atrax*, *Hadronyche* and *Illawarra*) and the far more diverse Araneomorphs (main clinically important species in the genera *Latrodectus* (widow spiders), *Loxosceles* (brown recluse spiders) and *Phoneutria* (banana or wandering spiders)).

**Clinical features and management**

While spiders and spider bites are common, only those genera noted above commonly cause medically significant effects. In most cases this is a neuroexcitatory envenoming, sometimes similar to severe scorpion envenoming (notable from Australian funnel web spiders), but the recluse spiders cause an often painless bite that develops into local skin necrosis and sometimes a systemic illness similar to that caused by the Iranian scorpion, *H. lepturus*, and with similar lethal potential.

For most of these spiders, antivenom remains the key treatment and is life-saving in some cases. Recent studies suggesting that anti-*Latrodectus* antivenom is ineffective have not been confirmed by independent studies and are in contrast to decades of positive clinical experience.

### Paralysis ticks

Most ticks are vectors for disease but a few species in Australia, North America and parts of Africa can cause flaccid paralysis. Toxins in the saliva act as potent pre-synaptic neurotoxins that can cause gradual-onset ascending flaccid paralysis.

There are no antivenoms for tick paralysis. Treatment is based on removal of all ticks and supportive care, including intubation/ventilation where required. The paralysis usually resolves by about 48 hours following removal of all ticks.

### Venomous insects

A number of insects are venomous but very few cause significant envenoming in humans.

#### Venomous lepidopterans

The *Lonomia* caterpillars of South America, especially Brazil, have numerous protective venomous spines that, on contact with the skin, can discharge a potent procoagulant venom that can cause a progressive and sometimes fatal consumptive coagulopathy, with terminal haemorrhagic and/or organ failure events. Treatment includes use of a Brazilian specific antivenom and supportive care.

#### Venomous hymenopterans

Many bees, wasps, hornets and some ants have modified ovipositors in the abdomen that act as stings, attached to venom glands. The quantity of venom injected in a single sting is insufficient to cause significant envenomation, but as many of these venoms are potently allergenic, it can cause severe and sometimes fatal anaphylaxis in sensitised persons (p. 75). Massed stings by hundreds of these insects in a swarm, however, can cause life-threatening systemic envenoming, often with intravascular haemolysis, DIC, shock and multi-organ failure. ‘Africanised’ bees are a particular risk for such attacks in South
America and now in parts of North America. The giant wasps and hornets of Asia can similarly cause systemic envenoming with multiple attacks. Invasive ants, such as Solenopsis spp., are colonising new regions and can cause both allergic reactions and unpleasant local reactions.

### Marine venomous and poisonous animals

The marine environment is dominated by animal life, and many species utilise toxins, either self-produced or taken up from the environment, to arm themselves for either defence or predation. Many of these animals can cause adverse effects in humans, either as a direct venom effect on bites/stings (venomous spiny fish, sea snakes, stingrays, jellyfish, sea urchins, some starfish, cone snails, selected octopuses etc.), or through poisoning if eaten (fugu, ciguatera, scombroid, several types of shellfish poisoning; p. 149).

For venomous marine animals, there is antivenom available only for sea snakes, which can cause rhabdomyolysis and paralytic neurotoxicity; box jellyfish, which can cause very rapid cardiac collapse; and stonefish, which cause intense sting-site pain. In general, marine venoms respond to heat; thus a hot water immersion or shower (about 45°C) is effective at reducing local pain, particularly for jellyfish, stinging fish and stingray stings. For stingray stings, the venom may cause local tissue damage both through sting trauma and a venom effect; wounds penetrating the abdomen or chest are potentially lethal and wounds should be adequately explored, cleaned and allowed to heal by secondary intention. For bites by the blue-ringed octopus and stings by cone snails, rapid-acting venom can cause early cardiovascular collapse and flaccid paralysis. Supportive care is crucial in ensuring survival from these potentially lethal and seemingly trivial local wounds. Sea urchin and venomous starfish wounds can result in multiple penetrating spines, which cause pain and act as a nidus for secondary infection, but surgical removal of spines can be difficult and unrewarding.

#### Websites

toxinology.com Clinical toxicology guide from the University of Adelaide.
Environmental medicine deals with the interactions between the environment and human health. While previously concerned mainly with controlling infectious diseases, the focus at present is predominantly on the multiple physical, chemical, biological and social factors that pose risks to human health. As the environment continually alters, whether through population growth, economic development or climate change, it plays an important role in disease causation – one that may increase over time. This chapter deals principally with acute effects of environmental hazards on individuals and should be read in conjunction with the chapters on Poisoning (Ch. 7) and Acute Medicine and Critical Illness (Ch. 10). Chapter 5 deals with more general effects of environmental factors on population health.

Radiation exposure

Radiation includes ionising (Fig. 9.1) and non-ionising radiations (ultraviolet (UV), visible light, laser, infrared and microwave). While global industrialisation and the generation of fluorocarbons have raised concerns about loss of the ozone layer, leading to an increased exposure to UV rays, and disasters such as the Chernobyl and Fukushima nuclear power station explosions have demonstrated the harm of ionising radiation, it is important to remember that it can be harnessed for medical benefit. Ionising radiation is used in X-rays, computed tomography (CT), radionuclide scans and radiotherapy, and non-ionising UV for therapy in skin diseases and laser therapy for diabetic retinopathy.

Types of ionising radiation

These include charged subatomic alpha and beta particles, uncharged neutrons or high-energy electromagnetic radiations such as X-rays and gamma rays. When they interact with atoms, energy is released and the resulting ionisation can lead to molecular damage. The clinical effects of different forms of radiation depend on their range in air and tissue penetration (Fig. 9.1).

Dosage and exposure

The dose of radiation is based on the energy absorbed by a unit mass of tissue and is measured in grays (Gy), with 1 Gy representing 1 J/kg. To take account of different types of radiation and variations in the sensitivity of various tissues, weighting factors are used to produce a unit of effective dose, measured in sieverts (Sv). This value reflects the absorbed dose weighted for the damaging effects of a particular form of radiation and is most valuable in evaluating the long-term effects of exposure.

‘Background radiation’ refers to our exposure to naturally occurring radioactivity (e.g. radon gas and cosmic radiation). This produces an average annual individual dose of approximately 2.6 mSv per year, although this figure varies according to local geology.

Effects of radiation exposure

Effects on the individual are classified as either deterministic or stochastic.

Deterministic effects

Deterministic (threshold) effects occur with increasing severity as the dose of radiation rises above a threshold level. Tissues with actively dividing cells, such as bone marrow and gastrointestinal mucosa, are particularly sensitive to ionising radiation. Lymphocyte depletion is the most sensitive marker of bone marrow injury, and after exposure to a fatal dose, marrow aplasia is a common cause of death. However, gastrointestinal mucosal toxicity may cause earlier death due to profound diarrhoea, vomiting, dehydration and sepsis. The gonads are highly radiosensitive and radiation may result in temporary or permanent sterility. Eye exposure can lead to cataracts and the skin is susceptible to radiation burns. Irradiation of the lung may induce acute inflammatory reactions or pulmonary fibrosis, and irradiation of the central nervous system may cause permanent neurological deficit. Bone necrosis and lymphatic fibrosis are characteristic following regional irradiation, particularly for breast cancer. The thyroid gland is not inherently sensitive but its ability to concentrate iodine makes it susceptible to damage after exposure to relatively low doses of radioactive iodine isotopes, such as those released from Chernobyl.

Stochastic effects

Stochastic (chance) effects occur with increasing probability as the dose of radiation increases. Carcinogenesis represents a stochastic effect. With acute exposures, leukaemias may arise after an interval of around 2–5 years and solid tumours after an...
interval of about 10–20 years. Thereafter the incidence rises with time. An individual’s risk of developing cancer depends on the dose received, the time to accumulate the total dose and the interval following exposure.

### Management of radiation exposure

Exposed people should be removed from ongoing exposure ("get inside, stay inside"), and should take off affected clothing and shower to stop further contamination. If contamination of food and water supplies may have occurred, only bottled water and food in sealed containers should be consumed. The principal problems after large-dose exposures are maintenance of adequate hydration, control of sepsis and management of marrow aplasia. Associated injuries such as thermal burns need specialist management within 48 hours of active resuscitation. Internal exposure to radioisotopes should be treated with chelating agents (such as Prussian blue used to chelate $^{137}$cesium after ingestion). White-cell colony stimulation and haematopoietic stem cell transplantation may need to be considered for marrow aplasia.

### Extremes of temperature

#### Thermoregulation

Body heat is generated by basal metabolic activity and muscle movement, and lost by conduction (which is more effective in water than in air), convection, evaporation and radiation (most important at lower temperatures when other mechanisms conserve heat) (Box 9.1). Body temperature is controlled in the hypothalamus, which is directly sensitive to changes in core temperature and indirectly responds to temperature-sensitive neurons in the skin. The normal ‘set-point’ of core temperature is tightly regulated within the range 37±0.5°C, which is necessary to preserve the normal function of many enzymes and other metabolic processes. The temperature set-point is increased in response to infection (p. 218).

#### Hypothermia

Hypothermia exists when the body’s normal thermal regulatory mechanisms are unable to maintain heat in a cold environment and core temperature falls below 35°C (Fig. 9.2). Moderate hypothermia occurs below 32°C and severe hypothermia below 28°C. Other systems define hypothermia on the basis of symptoms rather than absolute temperature. While infants are susceptible to hypothermia because of their poor thermoregulation and high body surface area to weight ratio, it is the elderly who are at highest risk (Box 9.2). Hypothyroidism is often a contributory factor in old age, while

*These losses are dependent on the relative ambient and skin temperatures.

In a cold environment, protective mechanisms include cutaneous vasoconstriction and shivering; however, any muscle activity that involves movement may promote heat loss by increasing convective loss from the skin, and respiratory heat loss by stimulating ventilation. In a hot environment, sweating is the main mechanism for increasing heat loss. This usually occurs when the ambient temperature rises above 32.5°C or during exercise.

#### Hypothermia

Hypothermia exists when the body’s normal thermal regulatory mechanisms are unable to maintain heat in a cold environment and core temperature falls below 35°C (Fig. 9.2). Moderate hypothermia occurs below 32°C and severe hypothermia below 28°C. Other systems define hypothermia on the basis of symptoms rather than absolute temperature. While infants are susceptible to hypothermia because of their poor thermoregulation and high body surface area to weight ratio, it is the elderly who are at highest risk (Box 9.2). Hypothyroidism is often a contributory factor in old age, while
### 9.2 Thermoregulation in old age

- **Age-associated changes:** Impairments in vasomotor function, skeletal muscle response and sweating mean that older people react more slowly to changes in temperature.
- **Increased comorbidity:** thermoregulatory problems are more likely in the presence of pathology such as atherosclerosis and hypothyroidism, and medication such as sedatives and hypnotics.
- **Hypothermia:** this may arise as a primary event, but more commonly complicates other acute illness, e.g. pneumonia, stroke or fracture.
- **Ambient temperature:** financial pressures and older equipment may result in inadequate heating during cold weather.

### Clinical features

Diagnosis is dependent on recognition of the environmental circumstances and measurement of core (rectal) body temperature. Clinical features depend on the degree of hypothermia (Fig. 9.2).

In a cold patient, it is very difficult to diagnose death reliably by clinical means. It has been suggested that, in extreme environmental conditions, irreversible hypothermia is probably present if there is asystole (no carotid pulse for 1 min), the chest and abdomen are rigid, the core temperature is <13°C and serum potassium is >12 mmol/L. However, in general, resuscitative measures should continue until the core temperature is normal and only then should a diagnosis of brain death be considered (p. 211).

### Investigations

Blood gases, a full blood count, electrolytes, chest X-ray and electrocardiogram (ECG) are all essential investigations. Haemoconcentration and metabolic acidosis are common, and the ECG may show characteristic J waves, which occur at the junction of the QRS complex and the ST segment (Fig. 9.3). Cardiac arrhythmias, including ventricular fibrillation, may occur. Although the arterial oxygen tension may be normal when measured at room temperature, the arterial PO<sub>2</sub> in the blood falls by 7% for each 1°C fall in core temperature. Serum aspartate aminotransferase and creatine kinase may be elevated secondary to muscle damage and the serum amylase is often high due to subclinical pancreatitis. If the cause of hypothermia is not obvious, additional investigations for thyroid and pituitary–adrenal dysfunction (p. 633), hypoglycaemia (p. 725) and the possibility of drug intoxication (p. 134) should be performed.

### Management

Following resuscitation, the objectives of management are to rewarm the patient in a controlled manner while treating associated hypoxia (by oxygenation and ventilation if necessary), fluid and electrolyte disturbance, and cardiovascular abnormalities, particularly arrhythmias. Careful handling is essential to avoid precipitating the latter. The method of rewarming is dependent not on the absolute core temperature, but on haemodynamic stability and the presence or absence of an effective cardiac output.

### Mild hypothermia

Outdoors, continued heat loss is prevented by sheltering the patient from the cold, replacing wet clothing, covering the head and insulating him or her from the ground. Once in hospital, even in the presence of profound hypothermia, if there is an effective cardiac output then forced-air rewarming, heat packs placed in axillae and groins and around the abdomen, inhaled warmed air and correction of fluid and electrolyte disturbances are usually sufficient. Rewarming rates of 1–2°C per hour are effective in leading to a gradual and safe return to physiological normality. Underlying conditions should be treated promptly (e.g. hypothyroidism with triiodothyronine 10 μg IV 3 times daily; p. 640).

### Severe hypothermia

In the case of severe hypothermia (<28°C), patients with cardiopulmonary arrest (non-perfusing rhythm), or those with cardiac instability (systolic blood pressure <90 mmHg or ventricular arrhythmias), the aim is to restore perfusion, and rapid rewarming at a rate of >2°C per hour is required. This is best achieved by cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO). If these are unavailable, then veno–veno haemofiltration, and pleural, peritoneal, thoracic or bladder lavage with warmed fluids are alternatives. Direct heat sources, such as hot water or heat pats, should be used with caution, as these can provoke cardiac arrhythmias or cause burns. Monitoring of cardiac rhythm and arterial blood gases, including H<sup>+</sup> (pH), is essential. Significant acidosis may require correction (p. 364).

### Cold injury

#### Freezing cold injury (frostbite)

This represents the direct freezing of body tissues and usually affects the extremities: in particular, the fingers, toes, ears and face. Risk factors include smoking, peripheral vascular disease, dehydration and alcohol consumption. The tissues may become anaesthetised before freezing and, as a result, the injury often goes unrecognised at first. Frostbitten tissue is initially pale and doughy to the touch and insensitive to pain (Fig. 9.4). Once frozen, the tissue is hard.

Rewarming should not occur until it can be achieved rapidly in a water bath. Give oxygen and aspirin 300 mg as soon as possible. Frostbitten extremities should be rewarmed in warm water at 37–39°C, with antiseptic added. Adequate analgesia is necessary, as rewarming is very painful. Vasodilators such as...
Heat-related illness

When generation of heat exceeds the body’s capacity for heat loss, core temperature rises. Non-exertional heat illness (NEHI) occurs with a high environmental temperature in those with attenuated thermoregulatory control mechanisms: the elderly, the young, those with comorbidity or those taking drugs that affect thermoregulation (particularly phenothiazines, diuretics and alcohol). Exertional heat illness (EHI), on the other hand, typically develops in athletes when heat production exceeds the body’s ability to dissipate it.

Acclimatisation mechanisms to environmental heat include stimulation of the sweat mechanism with increased sweat volume, reduced sweat sodium content and secondary hyperaldosteronism to maintain body sodium balance. The risk of heat-related illness falls as acclimatisation occurs. Heat illness can be prevented to a large extent by adequate replacement of salt and water, although excessive water intake alone should be avoided because of the risk of dilutional hyponatraemia (p. 357).

A spectrum of illnesses occurs in the heat (see Fig. 9.2). The cause is usually obvious but the differential diagnosis should be considered (Box 9.3).

**Heat cramps**

These painful muscle contractions occur following vigorous exercise and profuse sweating in hot weather. There is no elevation of core temperature. The mechanism is considered to be extracellular sodium depletion as a result of persistent sweating, exacerbated by replacement of water but not salt. Symptoms usually respond rapidly to rehydration with oral rehydration salts or intravenous saline.

**Heat syncope**

This is similar to a vasovagal faint (p. 181) and is related to peripheral vasodilatation in hot weather.

**Heat exhaustion**

Heat exhaustion occurs with prolonged exertion in hot and humid weather, profuse sweating and inadequate salt and water replacement. There is an elevation in core (rectal) temperature to between 37°C and 40°C, leading to the clinical features shown in Figure 9.2. Blood analyses may show evidence of dehydration with mild elevation of the blood urea, sodium and haematocrit. Treatment involves removal of the patient from the heat, and active evaporative cooling using tepid sprays and fanning (‘strip–spray–fan’). Fluid losses are replaced with either oral rehydration mixtures or intravenous saline.

**Heat stroke**

Heat stroke occurs when the core body temperature rises above 40°C and is a life-threatening condition. The symptoms of heat exhaustion progress to include headache, nausea and vomiting. Neurological manifestations include a coarse muscle tremor and confusion, aggression or loss of consciousness. The patient’s skin feels very hot, and sweating is often absent due to failure of thermoregulatory mechanisms. Complications include hypovolaemic shock, lactic acidosis, disseminated intravascular coagulation, rhabdomyolysis, hepatic and renal failure, and pulmonary and cerebral oedema.

Duration of hyperthermia is key to the outcome and immediate cooling should begin at the scene, before transfer to hospital. The aim should be to reduce core temperature by >0.2°C per minute to approximately 39°C, while avoiding overshooting and hypothermia. The patient should be resuscitated with evaporative or convective cooling. Fluid resuscitation with crystalloid intravenous fluids should be instituted but solutions containing potassium

**Non-freezing cold injury (trench or immersion foot)**

This results from prolonged exposure to cold, damp conditions. The limb (usually the foot) appears cold, ischaemic and numb, but there is no freezing of the tissue. On rewarming, the limb appears mottled and thereafter becomes hyperaemic, swollen and painful. Recovery may take many months, during which period there may be chronic pain and sensitivity to cold. The pathology remains uncertain but probably involves endothelial injury. Gradual rewarming is associated with less pain than rapid rewarming. The pain and associated paraesthesia are difficult to control with conventional analgesia and may require amitriptyline (50 mg nocte), best instituted early. The patient is at risk of further damage on subsequent exposure to the cold.

**Chilblains**

Chilblains are tender, red or purplish skin lesions that occur in the cold and wet. They are often seen in horse riders, cyclists and swimmers, and are more common in women than men. They are short-lived and, although painful, not usually serious.

![Fig. 9.4 Frostbite in a female Everest sherpa.](image)

**Differential diagnosis in patients with elevated core body temperature**

- Heat illness (heat exhaustion, heat stroke)
- Sepsis, including meningitis
- Malaria
- Drug overdose
- Serotonin syndrome (pp. 139 and 1199)
- Malignant hyperpyrexia
- Thyroid storm (p. 639)
should be avoided. Intravenous dextrose may be necessary, as hypoglycaemia can occur. Appropriate monitoring of fluid balance, including central venous pressure, is important, as over-aggressive fluid replacement may precipitate pulmonary oedema or further metabolic disturbance. Investigations for complications include routine haematology and biochemistry, coagulation screen, hepatic transaminases (aspartate aminotransferase and alanine aminotransferase), creatine kinase and chest X-ray. Once emergency treatment is established, heat stroke patients are best managed in intensive care.

Heat stroke is an emergency with a significant mortality. However, where temperatures can be reduced to <40°C within 30 minutes of collapse, death rates can approach zero. Patients who have had core temperatures of >40°C should be monitored carefully for later onset of rhabdomyolysis, renal damage and other complications before discharge from hospital. Clear advice to avoid heat and heavy exercise during recovery is important.

### Illnesses at high altitude

Ascent to altitudes up to 2500 m or travel in a pressurised aircraft cabin is harmless to healthy people. Above 2500 m high-altitude illnesses may occur in previously healthy people, and above 3500 m these become common. Sudden ascent to altitudes above 6000 m, as experienced by aviators, balloonists and astronauts, may result in decompression illness with the same clinical features as seen in divers (see below), or even loss of consciousness. However, most altitude illness occurs in travellers and mountaineers.

#### Acute mountain sickness

Acute mountain sickness (AMS) is a syndrome comprised principally of headache, together with fatigue, anorexia, nausea and vomiting, difficulty sleeping or dizziness. Ataxia and peripheral oedema may be present. The aetiology of AMS is not fully understood but it is thought that hypoxaemia increases cerebral blood flow and hence intracranial pressure. Symptoms occur within 6–12 hours of an ascent and vary in severity from trivial to completely incapacitating. The incidence in travellers to 3000 m may be 40–50%, depending on the rate of ascent.

Treatment of mild cases consists of rest and simple analgesia; symptoms usually resolve after 1–3 days at a stable altitude, but may recur with further ascent. Occasionally, there is progression to cerebral oedema. Persistent symptoms indicate the need to descend but may respond to acetazolamide, a carbonic anhydrase inhibitor that induces a metabolic acidosis and stimulates ventilation; acetazolamide may also be used as prophylaxis if a rapid ascent is planned.

#### High-altitude cerebral oedema

The cardinal symptoms of high-altitude cerebral oedema (HACE) are ataxia and altered consciousness. HACE is rare, life-threatening and usually preceded by AMS. In addition to features of AMS, the patient suffers confusion, disorientation, visual disturbance, lethargy and ultimately loss of consciousness. Papilloedema and retinal haemorrhages are common and focal neurological signs may be found.

Treatment is directed at improving oxygenation. Descent is essential and dexamethasone (8 mg immediately and 4 mg 4 times daily) should be given. If descent is impossible, oxygen therapy in a portable pressurised bag may be helpful.

#### High-altitude pulmonary oedema

High-altitude pulmonary oedema (HAPE) is a life-threatening condition that usually occurs in the first 4 days after ascent above 2500 m. Unlike HACE, HAPE may occur de novo without the preceding signs of AMS. Presentation is with symptoms of dry cough, exertional dyspnoea and extreme fatigue. Later, the cough becomes wet and sputum may be blood-stained. Tachycardia and tachypnoea occur at rest and crepitations may often be heard in both lung fields. There may be profound hypoxaemia, pulmonary hypertension and radiological evidence...
of diffuse alveolar oedema. It is not known whether the alveolar oedema is a result of mechanical stress on the pulmonary capillaries associated with the high pulmonary arterial pressure, or an effect of hypoxia on capillary permeability. Reduced arterial oxygen saturation is not diagnostic but is a marker for disease progression.

Treatment is directed at reversal of hypoxia with immediate descent and oxygen administration. Nifedipine (20 mg 4 times daily) should be given to reduce pulmonary arterial pressure, and oxygen therapy in a portable pressurised bag should be used if descent is delayed.

**Chronic mountain sickness (Monge’s disease)**
This occurs on prolonged exposure to altitude and has been reported in residents of Colorado, South America and Tibet. Patients present with headache, poor concentration and other signs of polycythaemia. The haemoglobin concentration is high (>200 g/L) and the haematocrit raised (>65%). Affected individuals are cyanosed and often have finger clubbing.

**High-altitude retinal haemorrhage**
This occurs in over 30% of trekkers at 5000 m. The haemorrhages are usually asymptomatic and resolve spontaneously. Visual defects can occur with haemorrhage involving the macula but there is no specific treatment.

**Venous thrombosis**
This has been reported at altitudes of >6000 m. Risk factors include dehydration, inactivity and the cold. The use of the oral contraceptive pill at high altitude should be considered carefully, as this is an additional risk factor.

**Refractory cough**
A cough at high altitude is common and usually benign. It may be due to breathing dry, cold air and to increased mouth breathing, with consequent dry oral mucosa. This may be indistinguishable from the early signs of HAPE.

**Air travel**
Commercial aircraft usually cruise at 10 000–12 000 m, with the cabin pressurised to an equivalent of around 2400 m. At this altitude, the partial pressure of oxygen is 16 kPa (120 mmHg), leading to a PaO₂ in healthy people of 7.0–8.5 kPa (53–64 mmHg). Oxygen saturation is also reduced but to a lesser degree (see Fig. 9.5). Although well tolerated by healthy people, this degree of hypoxia may be dangerous in patients with respiratory disease.

**Advice for patients with respiratory disease**
The British Thoracic Society has published guidance on the management of patients with respiratory disease who want to fly. Specialist pre-flight assessment is advised for all patients who have hypoxaemia (oxygen saturation <95%) at sea level, and includes spirometry and a hypoxic challenge test with 15% oxygen (performed in hospital). Air travel may have to be avoided or undertaken only with inspired oxygen therapy during the flight. Asthmatic patients should be advised to carry their inhalers in their hand baggage. Following pneumothorax, flying should be avoided while air remains in the pleural cavity, but can be considered after proven resolution or definitive (surgical) treatment.

**Advice for other patients**
Other circumstances in which patients are more susceptible to hypoxia require individual assessment. These include cardiac arrhythmia, sickle-cell disease and ischaemic heart disease. Most airlines decline to carry pregnant women after the 36th week of gestation. In complicated pregnancies it may be advisable to avoid air travel at an earlier stage. Patients who have had recent abdominal surgery, including laparoscopy, should avoid flying until all intraperitoneal gas is reabsorbed. Divers should not fly for 24 hours after a dive requiring decompression stops.

Ear and sinus pain due to changes in gas volume are common but usually mild, although patients with chronic sinusitis and otitis media may need specialist assessment. A healthy mobile tympanic membrane visualised during a Valsalva manoeuvre usually suggests a patent Eustachian tube.

On long-haul flights, patients with diabetes mellitus may need to adjust their insulin or oral hypoglycaemic dose according to the timing of in-flight and subsequent meals (p. 750). Advice is available from Diabetes UK and other websites. Patients should be able to provide documentary evidence of the need to carry needles and insulin.

**Deep venous thrombosis**
Air travellers have an increased risk of venous thrombosis (p. 973), due to a combination of factors, including loss of venous emptying because of prolonged immobilisation (lack of muscular activity) and reduced barometric pressure on the tissues, together with haemoconcentration as a result of oedema and perhaps a degree of hypoxia-induced diuresis.

Venous thrombosis can probably be prevented by avoiding dehydration and excess alcohol, and by exercising muscles during the flight. Without a clear cost–benefit analysis, prophylaxis with aspirin or heparin cannot be recommended routinely, but may be considered in high-risk cases.

**Under water**

**Drowning and near-drowning**
Drowning is defined as death due to asphyxiation following immersion in a fluid, while near-drowning is defined as survival for longer than 24 hours after suffocation by immersion. Drowning remains a common cause of accidental death throughout the world and is particularly common in young children (Box 9.4). In about 10% of cases, no water enters the lungs and death follows intense laryngospasm (‘dry’ drowning). Prolonged immersion in cold water, with or without water inhalation, results in a rapid fall in core body temperature and hypothermia (p. 165).

Following inhalation of water, there is a rapid onset of ventilation–perfusion imbalance with hypoxaemia, and the development of venous thrombosis.

of diffuse pulmonary oedema. Fresh water is hypotonic and, although rapidly absorbed across alveolar membranes, impairs surfactant function, which leads to alveolar collapse and right-to-left shunting of unoxygenated blood. Absorption of large amounts of hypotonic fluid can result in hyaemolysis. Salt water is hypertonic and inhalation provokes alveolar oedema, but the overall clinical effect is similar to that of freshwater drowning.

**Clinical features**

Those rescued alive (near-drowning) are often unconscious and not breathing. Hypoxaemia and metabolic acidosis are inevitable features. Acute lung injury usually resolves rapidly over 48–72 hours, unless infection occurs (Fig. 9.6). Complications include dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac arrhythmias. A small number of patients, mainly those rescued alive (near-drowning) are often unconscious and not breathing. Hypoxaemia and metabolic acidosis are inevitable features. Acute lung injury usually resolves rapidly over 48–72 hours, unless infection occurs (Fig. 9.6). Complications include dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac arrhythmias. A small number of patients, mainly dehydration, hypotension, haemoptysis, rhabdomyolysis, renal failure and cardiac arrhythmias. A small number of patients, mainly the more severely ill, progress to develop the acute respiratory distress syndrome (ARDS; p. 198).

Survival is possible after immersion for up to 30 minutes in very cold water, as the rapid development of hypothermia after immersion may be protective, particularly in children. Long-term outcome depends on the severity of the cerebral hypoxic injury and is predicted by the duration of immersion, delay in resuscitation, intensity of acidosis and the presence of cardiac arrest.

**Management**

Initial management requires cardiopulmonary resuscitation with administration of oxygen and maintenance of the circulation (p. 456). It is important to clear the airway of foreign bodies and protect the cervical spine. Continuous positive airways pressure (CPAP; p. 202) should be considered for spontaneously breathing patients with oxygen saturations of <94%. Observation is required for a minimum of 24 hours. Prophylactic antibiotics are only required if exposure was to obviously contaminated water.

---

**Diving-related illness**

The underwater environment is extremely hostile. Other than drowning, most diving illness is related to changes in barometric pressure and its effect on gas behaviour.

Ambient pressure under water increases by 101 kPa (1 atmosphere, 1 ata) for every 10 metres of seawater (msw) depth. As divers descend, the partial pressures of the gases they are breathing increase (Box 9.5), and the blood and tissue concentrations of dissolved gases rise accordingly. Nitrogen is a weak anaesthetic agent, and if the inspiratory pressure of nitrogen is allowed to increase above 320 kPa (3.2 ata; i.e. a depth of approximately 30 msw), it produces ‘narcosis’, resulting in impairment of cognitive function and manual dexterity, not unlike alcohol intoxication. For this reason, compressed air can be used only for shallow diving. Oxygen is also toxic at inspired pressures above approximately 40 kPa (0.4 ata; inducing apprehension, muscle twitching, euphoria, sweating, tinnitus, nausea and vertigo), so 100% oxygen cannot be used as an alternative. For dives deeper than approximately 30 msw, mixtures of oxygen with nitrogen and/or helium are used.

While drowning remains the most common diving-related cause of death, another important group of disorders usually present once the diver returns to the surface: decompression illness (DCI) and barotrauma.

**Clinical features**

**Decompression illness**

This includes decompression sickness (DCS) and arterial gas embolism (AGE). While the vast majority of symptoms of DCI present within 6 hours of a dive, they can also be provoked by flying (further decompression), and thus patients may present to medical services at sites far removed from the dive.

Exposure of individuals to increased partial pressures of nitrogen results in additional nitrogen being dissolved in body tissues; the amount dissolved depends on the depth/pressure and on the duration of the dive. On ascent, the tissues become supersaturated with nitrogen, and this places the diver at risk of producing a critical quantity of gas (bubbles) in tissues if the ascent is too fast. The gas so formed may cause symptoms locally, peripherally due to bubbles passing through the pulmonary vascular bed (Box 9.6) or by embolisation elsewhere. Arterial embolisation may occur if the gas load in the venous system exceeds the lungs’ abilities to excrete nitrogen, or when bubbles pass through a patent foramen ovale (present asymptomatically

</table>
in 25–30% of adults; p. 531). Although DCS and AGE can be indistinguishable, their early treatment is the same.

Barotrauma
During the ascent phase of a dive, the gas in the diver’s lungs expands due to the decreasing pressure. The diver must therefore ascend slowly and breathe regularly; if ascent is rapid or the diver holds his/her breath, the expanding gas may cause lung rupture (pulmonary barotrauma). This can result in pneumomediastinum, pneumothorax or AGE as a result of gas passing directly into the pulmonary venous system. Other air-filled body cavities may be subject to barotrauma, including the ear and sinuses.

Management
The patient is nursed horizontally and airway, breathing and circulation are assessed. Treatment includes the following:

- **Progressive**
- **Static**
- **Relapsing**
- **Spontaneously improving**

### Manifestations

- Pain: often large joints, e.g. shoulder (‘the bends’)
- Neurological: any deficit is possible
- Audiovestibular: vertigo, tinnitus, nystagmus; may mimic inner ear barotrauma
- Pulmonary: chest pain, cough, haemoptysis, dyspnoea; may be due to arterial gas embolism (AGE)
- Cutaneous: itching, erythematous rash
- Lymphatic: tender lymph nodes, oedema
- Constitutional: headache, fatigue, general malaise

### Dive profile

- Depth
- Type of gas used
- Duration of dive

*Information required by diving specialists to decide appropriate treatment. See contact details on page 172.

The majority of patients make a complete recovery with treatment, although a small but significant proportion are left with neurological disability.

## Humanitarian crisis

Humanitarian crises are common. If the medical profession is to help, it must understand that the emergency treatment of a few sick and injured people is not always the priority and that there is a set of basic needs that must be addressed in order to do the most for the most.

A humanitarian crisis can take many forms: an environmental disaster, mass emigration due to drought, conflict or famine, a disease outbreak or any number of natural or man-made events. When this event overwhelms the resources of the affected country’s government, then the international community will often step in to help. Although a full examination of the subject is beyond the scope of this book, there are a few basic principles for managing a humanitarian crisis.

The response is broken down into four phases:
1. recognition (first week)
2. emergency response (first month)
3. consolidation phase (to crisis resolution or crisis containment)
4. handover and withdrawal.

### Recognition

Recognition of a disaster may be obvious in a sudden event such as an earthquake or a tidal wave, but less obvious in a disease outbreak or when it stems from internal conflict. The recognition phase is for the host nation rather than the international community, and requests for support will come from the affected country’s government.

### Emergency response

During the emergency phase, responders (whether international, governmental or the charity sector) will undertake an initial assessment of need, set objectives, mobilise resources, coordinate with other agencies and deploy to the crisis in order to deliver an initial response.

### Consolidation phase

The consolidation phase involves matching resources to need, dealing with the crisis, building resilience, supporting infrastructure (human and physical) and instituting systems to manage the ongoing health needs of the population.

### Handover and withdrawal

Once the crisis is under control and the country is able to manage within resources, a phased withdrawal can occur.

### Health-care priorities

When the normal infrastructure of a country or area fails, then populations are at risk, whether they shelter in place or flee, leading to mass migration. For health-care teams, rather than logisticians, rescue teams or security forces, there are well-defined priorities, which must be in place (Box 9.7). This must all occur during the emergency phase and is followed by the
implementation of a public health surveillance and reporting system and the mobilisation of local human resources, and their training and deployment during the consolidation phase in order to prepare for handover to the local competent authority and withdrawal.

9.7 Priorities in a humanitarian crisis

1. Assessment of population need
2. Safe water and sanitation
3. Food and nutrition
4. Shelter and warmth
5. Emergency health care
6. Immunisation of risk groups
7. Control of communicable diseases
8. Ongoing health surveillance and reporting
9. Training and deployment of indigenous health-care workers
10. Handover of responsibility to local authorities

10 VR Tallentire MJ MacMahon
Clinical examination in critical care

A **Airway**
- Is the airway patent?
- Is the end-tidal CO₂ trace normal?
- Are there any signs of airway obstruction?

B **Breathing**
- Is the physiology normal (SpO₂, respiratory rate, tidal volume)?
- What is the level of support?
- Are there any abnormal signs on chest examination?
- Review the ventilator settings, arterial blood gases and recent chest X-ray

C **Circulation**
- Is the physiology normal (heart rate, blood pressure, peripheral temperature, lactate, urine output)?
- How much support is required (inotrope, vasopressor)?

D **Disability**
- Level of responsiveness
- Delirium screen
- Pupillary responses
- Doses of sedative drugs

E **Enteral/exposure**
- Feeding regime
- Stool frequency
- Abdominal tenderness/bowel sounds present?

F **Fluids, electrolytes and renal system**
- What is the fluid balance?
- Urine volume and colour?
- Is there any oedema?
- Review the renal biochemistry and electrolyte levels

G **Glucose**
- What is the glucose level?
- Is insulin being administered?

H **Haematology**
- What are the haemoglobin/platelet levels?
- Are there any signs of bleeding?

I **Infection**
- What is the temperature?
- Review recent infective markers and trend
- What antibiotics are being given and what is the duration of treatment?
Bedside physiological data commonly monitored in an intensive care unit setting.

**Electrocardiography**
Heart rate, rhythm and QRS morphology

**Arterial line trace**
Size of the area under the curve is proportional to stroke volume
Narrow peaks suggest low stroke volume as shown here

**Oxygen saturation**
Saturation of haemoglobin measured by plethysmography (SpO₂). Gives an indication of adequacy of oxygenation, and the quality of tissue perfusion can also be inferred – a flat trace suggests poor peripheral perfusion

**Central venous pressure trace**
A non-specific guide to volume status and right ventricular function, Increased values in fluid overload and right ventricular failure

**Capnography**
Numerical value of end-tidal CO₂ (ETCO₂) is less than arterial PCO₂ (PaCO₂) by a variable amount. Shape of trace can signify airway displacement/obstruction, bronchospasm or a low cardiac output (as shown below)

### Plethysmography (SpO₂)

**Basic principles**
- Uses the different red and infrared absorption profiles of oxyhaemoglobin and deoxyhaemoglobin to estimate arterial oxyhaemoglobin saturation (SaO₂)
- Only pulsatile absorption is measured
- A poor trace correlates with poor perfusion

**Sources of error**
- Carboxyhaemoglobin – absorption profile is the same as oxyhaemoglobin: falsely elevated SpO₂
- Methaemoglobinaemia – SpO₂ will tend towards 85%
- Ambient light/poor application of probe/severe tricuspid regurgitation (pulsatile venous flow): falsely depressed SpO₂
- Reduced accuracy below 80% saturation
- Hyperbilirubinaemia does not affect SpO₂
Hospital medicine is becoming ever more specialised and people are living longer while accruing increasing numbers of chronic disease diagnoses. Rather than diminishing the role of the generalist, these factors paradoxically create a need for experts in the undifferentiated presentation. In the UK such physicians are known as ‘general physicians’, while in the US they are referred to as ‘hospitalists’.

Acute illness can present in a large variety of ways, depending on the nature of the illness, the underlying health of the individual, and their cultural and religious background. The skills of prompt diagnosis formation and provision of appropriate treatment rely on the integration of information from all the available sources, along with careful consideration of underlying chronic health problems.

Patients who deteriorate while in hospital make up a small but important cohort. If they are well managed, in-hospital cardiac arrest rates will be low. This can be achieved through the combined effects of prompt resuscitation and appropriate end-of-life decision-making. Early recognition of deterioration by ward teams and initial management by health-care professionals operating within a functioning rapid response system are the central tenets of any system designed to improve the outcomes of deteriorating ward patients.

Intensive care medicine has developed into a prominent specialty, central to the safe functioning of a modern acute hospital. Scientific endeavour has resulted in a much better understanding of the molecular pathophysiology of processes such as sepsis and acute respiratory distress syndrome, which account for much premature death worldwide.

**Acute medicine**

Acute medicine is the part of general medicine that is concerned with the immediate and early management of medical patients who require urgent care. As a specialty, it is closely aligned with emergency medicine and intensive care medicine, but is firmly rooted within general medicine. Acute physicians manage the adult medical take and lead the development of acute care pathways that aim to reduce variability, improve care and cut down hospital admissions.

**The decision to admit to hospital**

Every patient presenting to hospital should be assessed by a clinician who is able to determine whether or not admission is required. The requirement for admission is determined by many factors, including the severity of illness, the patient’s physiological reserve, the need for urgent investigations, the nature of proposed treatments and the patient’s social circumstances. In many cases, it is clear early in the assessment process that a patient requires admission. In such cases, a move into a medical receiving unit – often termed a medical admissions unit (MAU) or acute medical unit (AMU) – should be facilitated as soon as the initial assessment has been completed and urgent investigations and/or treatments have been instigated. In hospitals where such units do not exist, patients will need to be moved to a downstream ward once treatment has been commenced and they have been deemed sufficiently stable. Following the initial assessment, it may be possible to discharge stable patients home with a plan for early follow-up (such as a rapid-access specialist clinic appointment).

**Ambulatory care**

In some hospitals, it is increasingly possible for patient care to be coordinated in an ambulatory setting, negating the need for a patient to remain in hospital overnight. In the context of acute medicine, ambulatory care can be employed for conditions that are perceived by either the patient or the referring practitioner as requiring prompt clinical assessment by a competent decision-maker with access to appropriate diagnostic resources. The patient may return on several occasions for investigation, observation, consultation or treatment. Some presentations, such as a unilateral swollen leg (p. 186), lend themselves to this type of management (Box 10.1). If indicated, a Doppler ultrasound can be arranged, and patients with confirmed deep vein thromboses can be anticoagulated on an outpatient basis. Successful ambulatory care requires careful patient selection; while many patients may cherish the opportunity to sleep at home, others may find frequent trips to hospital or clinic too difficult due to frailty, poor mobility or transport difficulties.

**Presenting problems in acute medicine**

**Chest pain**

Chest pain is a common symptom in patients presenting to hospital. The differential diagnosis is wide (Box 10.2), and a

detailed history and thorough clinical examination are paramount to ensure that the subsequent investigative pathway is appropriate.

**Presentation**

Chest ‘pain’ is clearly a subjective phenomenon and may be described by patients in a variety of different ways. Whether the patient describes ‘pain’, ‘discomfort’ or ‘pressure’ in the chest, there are some key features that must be elicited from the history.

**Site and radiation**

Pain secondary to myocardial ischaemia is typically located in the centre of the chest. It may radiate to the neck, jaw, and upper or even lower arms. Occasionally, it may be experienced only at the sites of radiation or in the back. The pain of myocarditis or pericarditis is characteristically felt retrosternally, to the left of the sternum, or in the left or right shoulder. The severe pain of aortic dissection is typically central with radiation through to the back. Central chest pain may also occur with tumours affecting the mediastinum, oesophageal disease (p. 791) or disease of the thoracic aorta (p. 505). Pain situated over the left anterior chest and radiating laterally is unlikely to be due to cardiac ischaemia and may have many causes, including pleural or lung disorders, musculoskeletal problems or anxiety. Rarely, sharp, left-sided chest pain that is suggestive of a musculoskeletal problem may be a feature of mitral valve prolapse (p. 520).

**Characteristics**

Pleurisy, a sharp or ‘catching’ chest pain aggravated by deep breathing or coughing, is indicative of respiratory pathology, particularly pulmonary infection or infarction. However, the pain associated with myocarditis or pericarditis is often also described as ‘sharp’ and may ‘catch’ during inspiration, coughing or lying flat. It typically varies in intensity with movement and the phase of respiration. A malignant tumour invading the chest wall or ribs can cause gnawing, continuous local pain. The pain of myocardial ischaemia is typically dull, constricting, choking or ‘heavy’, and is usually described as squeezing, crushing, burning or aching. Patients often emphasise that it is a discomfort rather than a pain. Angina occurs during (not after) exertion and is promptly relieved (in less than 5 minutes) by rest. It may also be precipitated or exacerbated by emotion but tends to occur more readily during exertion, after a large meal or in a cold wind. In crescendo or unstable angina, similar pain may be precipitated by minimal exertion or at rest. The increase in venous return or preload induced by lying down may also be sufficient to provoke pain in vulnerable patients (decubitus angina). Patients with reversible airways obstruction, such as asthma, may also describe exertional chest tightness that is relieved by rest. This may be difficult to distinguish from myocardial ischaemia. Bronchospasm may be associated with wheeze, atopy and cough (p. 556). Musculoskeletal chest pain is variable in site and intensity but does not usually fall into any of the patterns described above. The pain may vary with posture or movement of the upper body, or be associated with a specific movement (bending, stretching, turning). Many minor soft tissue injuries are related to everyday activities, such as driving, manual work and sport.

**Onset**

The pain associated with myocardial infarction (MI) typically takes several minutes or even longer to develop to its maximal intensity; similarly, angina builds up gradually in proportion to the intensity of exertion. Pain that occurs after, rather than during, exertion is usually musculoskeletal or psychological in origin. The pain of aortic dissection (severe and ‘tearing’), massive pulmonary embolism (PE) or pneumothorax is usually very sudden in onset. Other causes of chest pain tend to develop more gradually, over hours or even days.

**Associated features**

The pain of MI, massive PE or aortic dissection is often accompanied by autonomic disturbance, including sweating, nausea and vomiting. Some patients describe a feeling of impending death, referred to as ‘angor animi’. Breathlessness, due to pulmonary congestion arising from transient ischaemic left ventricular dysfunction, is often a prominent feature of myocardial ischemia. Breathlessness may also accompany any of the respiratory causes of chest pain and can be associated with cough, wheeze or other respiratory symptoms. Patients with myocarditis or pericarditis may describe a prodromal viral illness. Gastrointestinal disorders, such as gastro-oesophageal reflux or peptic ulceration, may present with chest pain that is hard to distinguish from myocardial ischaemia; it may even be precipitated by exercise and be relieved by nitrates. However, it is usually possible to elicit a history relating chest pain to supine posture or eating, drinking or oesophageal reflux. The pain of gastro-oesophageal reflux often radiates to the interscapular region and dysphagia may be present. Severe chest pain arising after retching or vomiting, or following oesophageal instrumentation, should raise the possibility of oesophageal perforation.
Side. Local tenderness of the chest wall is likely to indicate musculoskeletal pain but can also be found in pulmonary infarction. Subdiaphragmatic inflammatory pathology, such as a liver abscess, cholecystitis or ascending cholangitis, can mimic pneumonia by causing fever, pleuritic chest pain and a small sympathetic pleural effusion, usually on the right. Likewise, acute pancreatitis can present with thoracic symptoms, and an amylase or lipase level should be requested where appropriate. It is imperative that the abdomen is examined routinely in all patients presenting with pleuritic chest pain.

Initial investigations
Chest X-ray, ECG and biomarkers (e.g. troponin, D-dimer) play a pivotal role in the evaluation of chest pain. However, indiscriminate ordering of such investigations may result in diagnostic confusion and over-investigation. The choice of investigation(s) is intimately linked to the history and examination findings. A chest X-ray and 12-lead ECG should be performed in the vast majority of patients presenting to hospital with chest pain. Pregnancy is not a contraindication to chest X-ray, but particular consideration should be given to whether the additional diagnostic information justifies breast irradiation.

The chest X-ray may confirm the suspected diagnosis, particularly in the case of pneumonia. Small pneumothoraces are easily missed, as are rib fractures or small metastatic deposits, and all should be considered individually during chest X-ray review. A widened mediastinum suggests acute aortic dissection but a normal chest X-ray does not exclude the diagnosis. Provided it has been more than 1 hour since the onset of pain, chest X-ray in oesophageal rupture may reveal subcutaneous emphysema, pneumomediastinum or a pleural effusion.

Patients with a history compatible with myocardial ischaemia require an urgent 12-lead ECG. Acute chest pain with ECG changes indicating a ST segment elevation myocardial infarction (STEMI) suggests that the patient is likely to benefit from immediate reperfusion therapy. Specific information relating to cocaine or amphetamine use should be sought, particularly in younger...
patients. In the context of a compatible history, an ECG showing ischaemic changes that do not meet STEMI criteria should prompt regular repeat ECGs and treatment for non-ST segment elevation myocardial infarction (NSTEMI)/unstable angina. Measurement of serum troponin concentration on admission is often helpful in cases where there is diagnostic doubt, but a negative result should always prompt a repeat sample 6–12 hours after maximal pain.

Acute coronary syndrome may be diagnosed with confidence in patients with a convincing history of ischaemic pain (Fig. 10.1) and either ECG evidence of ischaemia or an elevated serum troponin. If an elevated serum troponin is found in a patient who has an atypical history or is at low risk of ischaemic heart disease, then alternative causes of raised troponin should be considered (Box 10.3). Further management of acute coronary syndromes is discussed on page 498.

In the absence of convincing ECG evidence of myocardial ischaemia, other life-threatening causes of chest pain, such as aortic dissection, massive PE and oesophageal rupture, should be considered. Suspicion of aortic dissection (background of hypertension, trauma, pregnancy or previous aortic surgery) should prompt urgent thoracic computed tomography (CT) or transoesophageal echocardiography. An ECG in the context of massive PE most commonly reveals only a sinus tachycardia, but may show new right axis deviation, right bundle branch block or a dominant R wave in V1. The classical finding of S1Q3T3 (a deep S wave in lead I, with a Q wave and T wave inversion in lead III) is rare. If massive PE is suspected and the patient is haemodynamically unstable, a transthoracic echocardiogram, to seek evidence of right heart strain and exclude alternative diagnoses such as tamponade, is extremely useful.

If the patient is deemed to be at low risk of PE, a D-dimer test can be informative, as a negative result effectively excludes the diagnosis. The D-dimer test should be performed only if there is clinical suspicion of PE, as false-positive results can lead to unnecessary investigations. If the D-dimer is positive, there is high clinical suspicion, or there is other convincing evidence of PE (such as features of right heart strain on the ECG), prompt imaging should be arranged (p. 619 and Fig. 17.67).

**Acute breathlessness**

In acute breathlessness, the history, along with a rapid but careful examination, will usually suggest a diagnosis that can be confirmed by routine investigations including chest X-ray, 12-lead ECG and arterial blood gas (ABG) sampling.

**Presentation**

A key feature of the history is the speed of onset of breathlessness. Acute severe breathlessness (over minutes or hours) has a distinct differential diagnosis list to chronic exertional breathlessness. The presence of associated cardiovascular (chest pain, palpitations, sweating and nausea) or respiratory symptoms (cough, wheeze, haemoptysis, stridor) can narrow the differential diagnosis yet further. A previous history of left ventricular dysfunction, asthma or exacerbations of chronic obstructive pulmonary disease (COPD) is important. In the severely ill patient, it may be necessary to obtain the history from accompanying witnesses. In children, the possibility of inhalation of a foreign body (Fig. 10.2) or acute epiglottitis should always be considered.

**Clinical assessment**

Airway obstruction, anaphylaxis and tension pneumothorax require immediate identification and treatment. If any of these is suspected, treatment should not be delayed while additional investigations are performed, and anaesthetic support is likely to be required. In the absence of an immediately life-threatening cause, the following should be assessed and documented:

- level of consciousness
- degree of central cyanosis
- work of breathing (rate, depth, pattern, use of accessory muscles)
- adequacy of oxygenation (SpO2)
ability to speak (in single words or sentences)

cardiovascular status (heart rate and rhythm, blood pressure (BP) and peripheral perfusion).

Pulmonary oedema is suggested by a raised jugular venous pressure and bi-basal crackles or diffuse wheeze, while asthma or COPD is characterised by wheeze and prolonged expiration. A hyper-resonant hemithorax with absent breath sounds raises the possibility of pneumothorax, while severe breathlessness with normal breath sounds may indicate PE. Leg swelling may suggest cardiac failure or, if asymmetrical, venous thrombosis.

The presence of wheeze is not always indicative of bronchospasm. In acute left heart failure, an increase in the left ventricular diastolic pressure causes the pressure in the left atrium, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the left ventricular diastolic pressure causes the pressure in the left atrium, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the left ventricular diastolic pressure, fluid moves from the capillaries into the interstitium. This stimulates respiration through a series of autonomic reflexes, producing rapid, shallow respiration, and congestion of the bronchial mucosa may cause wheeze (sometimes known as cardiac asthma). Sitting upright or standing may provide some relief by helping to reduce congestion at the apices of the lungs. The patient may be unable to speak and is typically distressed, agitated, sweaty and pale. Respiration is rapid, with recruitment of accessory muscles, coughing and wheezing. Sputum may be profuse, frothy and blood-streaked.

Any arrhythmia may cause breathlessness, but usually does so only if the heart is structurally abnormal, such as with the onset of atrial fibrillation in a patient with mitral stenosis. In such cases, the classic mid-diastolic rumbling murmur with pre-systolic accentuation may be heard. Patients sometimes describe chest tightness as ‘breathlessness’. However, myocardial ischaemia may also induce true breathlessness by provoking transient left ventricular dysfunction. When breathlessness is the dominant or sole feature of myocardial ischaemia, it is known as ‘angina equivalent’. A history of chest tightness or close correlation with exercise should be sought.

**Initial investigations**

As shown in Box 10.4, amalgamation of a clear history and thorough clinical examination with chest X-ray, ECG and ABG findings will usually indicate the primary cause of breathlessness. If bronchospasm is suspected, measurement of peak expiratory flow will assist in the assessment of severity and should be performed whenever possible. An ABG will often provide additional information to SpO₂ measurement alone, particularly if there is clinical evidence (drowsiness, delirium, asterixis) or a strong likelihood of hypercapnia. An acute rise in PaCO₂ will increase the HCO₃⁻ by only a small amount, resulting in inadequate buffering and acidemia. Renal compensation and a large rise in HCO₃⁻ will take at least 12 hours. In acute type II respiratory failure (p. 565), the rate of rise of PaCO₂ is a better indicator of severity than the absolute value.

An ABG is essential in the context of smoke inhalation to measure carboxyhaemoglobin level, and is central to the identification of metabolic acidosis or the diagnosis of psychogenic hyperventilation (Box 10.4). If ‘angina equivalent’ is suspected,
objective evidence of myocardial ischaemia from stress testing may help to establish the diagnosis.

**Syncope/presyncope**

The term ‘syncope’ refers to sudden loss of consciousness due to reduced cerebral perfusion. ‘Presyncope’ refers to lightheadedness, in which the individual thinks he or she may ‘black out’. Dizziness and presyncope are particularly common in old age (Box 10.5). Symptoms are disabling, undermine confidence and independence, and can affect a person’s ability to work or to drive.

There are three principal mechanisms that underlie recurrent presyncope or syncope:

- **cardiac syncope** due to mechanical cardiac dysfunction or arrhythmia
- **neurocardiogenic syncope** (also known as vasovagal or reflex syncope), in which an abnormal autonomic reflex causes bradycardia and/or hypotension
- **postural hypotension**, in which physiological peripheral vasoconstriction on standing is impaired, leading to hypotension.

There are, however, other causes of loss of consciousness, and differentiating syncope from seizure is a particular challenge. Psychogenic blackouts (also known as non-epileptic seizures or pseudoseizures) also need to be considered in the differential diagnosis.

### 10.5 Dizziness in old age

- **Prevalence**: common, affecting up to 30% of people aged >65 years.
- **Symptoms**: most frequently described as a combination of unsteadiness and lightheadedness.
- **Most common causes**: postural hypotension and cardiovascular disease. Many patients have more than one underlying cause.
- **Arrhythmia**: can present with lightheadedness either at rest or on activity.
- **Anxiety**: frequently associated with dizziness but rarely the only cause.
- **Falls**: multidisciplinary workup is required if dizziness is associated with falls.

### 10.6 Typical features of cardiac syncope, neurocardiogenic syncope and seizures

*N.B. Cardiac syncope can also cause convulsions by inducing cerebral anoxia.*

*Presentation*

The history from the patient and a witness is the key to establishing a diagnosis. The terms used for describing the symptoms associated with syncope vary so much among patients that they should not be taken for granted. Some patients use the term ‘blackout’ to describe a purely visual symptom, rather than loss of consciousness. Some may understand ‘dizziness’ to mean an abnormal perception of movement (vertigo), some will consider this a feeling of faintness, and others will regard it as unsteadiness. The clinician thus needs to elucidate the exact nature of the symptoms that the patient experiences. The potential differential diagnoses of syncope and presyncope, on the basis of the symptoms described, is shown in Figure 10.3.

The history should always be supplemented by a direct eye-witness account if available. Careful history with corroboration will usually establish whether there has been full consciousness, altered consciousness, vertigo, transient amnesia or something else. Attention should be paid to potential triggers (e.g. medication, micturition, exertion, prolonged standing), the patient’s appearance (e.g. colour, seizure activity), the duration of the episode, and the speed of recovery (Box 10.6). Cardiac syncope is usually sudden but can be associated with premonitory lightheadedness, palpatation or chest discomfort. The blackout is usually brief and recovery rapid. Exercise-induced syncope can be the presenting feature of a number of serious pathologies (such as hypertrophic obstructive cardiomyopathy or exercise-induced arrhythmia) and always requires further investigation. Neurocardiogenic syncope will often be associated with a situational trigger (such as pain or emotion), and the patient may experience flushing, nausea, malaise and clamminess for several minutes afterwards. Recovery is usually quick and without subsequent delirium, provided the patient has assumed a supine position. There is often some brief stiffening and limb-twitching, which requires differentiation from seizure-like movements. It is rare for syncope to cause injury or to cause amnesia after regaining awareness. Patients with seizures do not exhibit pallor, may have abnormal movements, usually take more than 5 minutes to recover and are often confused. Aspects of the history that can help to differentiate seizure from syncope are shown in Box 10.7.

A diagnosis of psychogenic blackout (also known as non-epileptic seizure, pseudoseizure or psychogenic seizure) may be suggested by specific emotional triggers, dramatic movements...

or vocalisation, or by very prolonged duration (hours). A history of rotational vertigo is suggestive of a labyrinthine or vestibular disorder (p. 1086). Postural hypotension is normally obvious from the history, with presyncope or, less commonly, syncope occurring within a few seconds of standing. The history should include enquiry about predisposing medications (diuretics, vasodilators, antidepressants) and conditions (such as diabetes mellitus and Parkinson’s disease).

**Clinical assessment**

Examination of the patient may be entirely normal, but may reveal clinical signs that favour one form of syncope. The systolic murmurs of aortic stenosis or hypertrophic obstructive
cardiomyopathy are important findings, particularly if paired with a history of lightheadedness or syncope on exertion. BP taken when supine and then after 1 and 3 minutes of standing may, when combined with symptoms, provide robust evidence of symptomatic postural hypotension.

Clinical suspicion of hypersensitive carotid sinus syndrome (sensitivity of carotid baroreceptors to external pressure such as a tight collar) should prompt monitoring of the ECG and BP during carotid sinus pressure, provided there is no carotid bruit or history of cerebrovascular disease. A positive cardio-inhibitory response is defined as a sinus pause of 3 seconds or more; a positive vasodepressor response is defined as a fall in systolic BP of more than 50 mmHg. Carotid sinus pressure will produce positive findings in about 10% of elderly individuals, but fewer than 25% of these experience spontaneous syncope. Symptoms should not, therefore, be attributed to hypersensitive carotid sinus syndrome unless they are reproduced by carotid sinus pressure.

**Initial investigations**

A 12-lead ECG is essential in all patients presenting with syncope or presyncope. Lightheadedness may occur with many arrhythmias, but blackouts (Stokes–Adams attacks, p. 477) are usually due to profound bradycardia or malignant ventricular tachyarrhythmias. The ECG may show evidence of conducting system disease (e.g. sinus bradycardia, atrioventricular block, bundle branch block), which would predispose a patient to bradycardia, but the key to establishing a diagnosis is to obtain an ECG recording **while symptoms are present**. Since minor rhythm disturbances are common, especially in the elderly, symptoms must occur at the same time as a recorded arrhythmia before a diagnosis can be made. Ambulatory ECG recordings are helpful only if symptoms occur several times per week. Patient-activated ECG recorders are useful for examining the rhythm in patients with recurrent dizziness but are not helpful in assessing sudden blackouts. When these investigations fail to establish a cause in patients with presyncope or syncope, an implantable ECG recorder can be sited subcutaneously over the upper left chest. This device continuously records the cardiac rhythm and will activate automatically if extreme bradycardia or tachycardia occurs. The ECG memory can also be tagged by the patient, using a hand-held activator as a form of ‘symptom diary’. Stored ECGs can be accessed by the implanting centre, using a telemetry device in a clinic, or using a home monitoring system via an online link.

Head-up tilt-table testing is a provocation test used to establish the diagnosis of vasovagal syncope. It involves positioning the patient supine on a padded table that is then tilted to an angle of 60–70° for up to 45 minutes, while the ECG and BP responses are monitored. A positive test is characterised by bradycardia (cardio-inhibitory response) and/or hypotension (vasodepressor response), associated with typical symptoms.

### Delirium

Delirium is a syndrome of transient, reversible cognitive dysfunction that is more common in old age. It is associated with high rates of mortality, complications and institutionalisation, and with longer lengths of stay. The recognised risk factors for delirium are shown in Box 10.8.

**Presentation**

Delirium manifests as a disturbance of arousal with global impairment of mental function, causing drowsiness with disorientation, perceptual errors and muddled thinking. The three broad subtypes of delirium – hypoactive, hyperactive and mixed – can be differentiated on the basis of psychomotor changes. Patients with hyperactive delirium are often agitated and restless, whereas hypoactive delirium can present as lethargy and sedation, and is frequently misdiagnosed as depression or dementia. Fluctuation is typical and delirium is often worse at night.

<thead>
<tr>
<th>10.9 How to make a diagnosis of delirium: the 4AT</th>
</tr>
</thead>
</table>
| 1. **Alertness**
| This includes patients who may be markedly drowsy (e.g. difficult to rouse and/or obviously sleepy during assessment) or agitated/hyperactive. Observe the patient. If asleep, attempt to wake with speech or gentle touch on shoulder. Ask the patient to state their name and address to assist rating: |
| Normal (fully alert, but not agitated, throughout assessment) |
| Mild sleepiness for <10 secs after waking, then normal |
| Clearly abnormal |
| 2. **AMT4** |
| Age, date of birth, place (name of the hospital or building), current year: |
| No mistakes |
| 1 mistake |
| ≥2 mistakes/untestable |
| 3. **Attention**
| Say to the patient: ‘Please tell me the months of the year in backwards order, starting at December.’ To assist initial understanding, one prompt of ‘What is the month before December?’ is permitted: |
| Achieves ≥7 months correctly |
| Starts but scores < 7 months/refuses to start |
| Untestable (cannot start because unwell, drowsy, inattentive) |
| 4. **Acute change or fluctuating course**
| Evidence of significant change or fluctuation in: alertness, cognition, other mental function (e.g. paranoia, hallucinations) arising over the last 2 weeks and still evident in last 24 hrs: |
| No |
| Yes |
| **Total 4AT score (maximum possible score 12)** |
| ≥4: possible delirium ± cognitive impairment |
| 1–3: possible cognitive impairment |
| 0: delirium or severe cognitive impairment unlikely (but delirium still possible if information in 4 incomplete) |

\[\text{AMT4} = \text{Abbreviated Mental Test 4}\]
night, when delirious patients can present significant management difficulties. Emotional disturbance (anxiety, irritability or depression) is common. History-taking from a delirious patient is frequently impossible, and every effort should be made to obtain a collateral history from a close friend or relative. As delirium is particularly common in patients with dementia, the collateral history should ask specifically about onset and course of delirium, along with any functional consequences in comparison to the patient’s norm.

**Clinical assessment**

In order to manage delirium effectively, the first step is to make a diagnosis. Tools such as the 4AT (Box 10.9) or the Confusion Assessment Method (CAM) can be used to detect delirium and differentiate it from dementia; such screening tools should be applied to all older patients admitted to hospital. Once a diagnosis of delirium has been established, attempts should be made to identify all of the reversible precipitating factors. Symptoms suggestive of a physical illness, such as an infection or stroke, should be elicited. An accurate drug and alcohol history is required, especially to ascertain whether any drugs have been recently stopped or started (see Fig. 10.4 for commonly implicated drugs). Although not always possible in its entirety, a full physical examination of all delirious patients should be attempted, noting in particular:

- pyrexia and any signs of infection in the chest, skin, abdomen or urine (on dipstick testing)
- oxygen saturation and signs of CO₂ retention
- signs of alcohol withdrawal or psychoactive drug use, such as tremor or sweating
- any focal neurological signs.

Certain psychiatric conditions, such as depressive pseudodementia and dissociative disorder, can easily be mistaken for delirium. Mental state examination is necessary to seek evidence of associated mood disorder, hallucinations, delusions or behavioural abnormalities. Examination should also include cognitive testing with a tool such as the Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA) (p. 1181).

**Investigations and management**

Common causes of delirium, along with appropriate investigative pathways, are shown in Figure 10.4. Alongside investigation and treatment of underlying causes, delirium and disorientation should be minimised by a well-lit and quiet environment, with hearing aids and glasses readily available. Good nursing is needed to preserve orientation, prevent pressure sores and falls, and maintain hydration, nutrition and continence. Sedatives may worsen delirium and should be used as a last resort. Resolution of delirium, particularly in the elderly, may be slow and incomplete. Many patients fail to recover to their pre-morbid level of cognition.

---

**Fig. 10.4 Common causes and investigation of delirium.** All investigations are performed routinely, except those in italics. *Tend to present over weeks to months rather than hours to days. The chest X-ray shows right mid- and lower zone consolidation. The CT scan shows a subdural haematoma. (COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; MI = myocardial infarction; SSRI = selective serotonin re-uptake inhibitor; UTI = urinary tract infection)
Headache

Headache is common and causes considerable worry amongst both patients and clinicians, but rarely represents sinister disease. The causes may be divided into primary or secondary, with primary headache syndromes being vastly more common (Box 10.10).

**Presentation**

The primary purpose of the history and clinical examination in patients presenting with headache is to identify the small minority of patients with serious underlying pathology. Key features of the history include the temporal evolution of a headache; a headache that reached maximal intensity immediately or within 5 minutes of onset requires rapid assessment for possible subarachnoid haemorrhage. Other ‘red flag’ symptoms are shown in Box 10.11.

It is important to establish whether the headache comes and goes, with periods of no headache in between (usually migraine), or whether it is present all or almost all of the time. Associated features, such as preceding visual symptoms, nausea/vomiting or photophobia/phonophobia, may support a diagnosis of migraine but others, such as progressive focal symptoms or constitutional upset like weight loss, may suggest a more sinister cause. The headache of cerebral venous thrombosis may be ‘throbbing’ or ‘band-like’ and associated with nausea, vomiting or hemiparesis. Raised intracranial pressure (ICP) headache tends to be worse in the morning and when lying flat or coughing, and associated with nausea and/or vomiting.

A description of neck stiffness along with headache and photophobia should raise the suspicion of meningitis (Box 10.12), although this may present in atypical ways in immunosuppressed, alcoholic or pregnant patients. The behaviour of the patient during headache is often instructive; migraine patients typically retire to bed to sleep in a dark room, whereas cluster headache often induces agitated and restless behaviour. The pain of a subarachnoid haemorrhage frequently causes significant distress.

Headache duration is also important to elicit; headaches that have been present for months or years are almost never sinister, whereas new-onset headache, especially in the elderly, is more of a concern. In a patient over 60 years with head pain localised to one or both temples, scalp tenderness or jaw claudication, referred pain from other structures (orbit, temporomandibular joint, neck)

---

### 10.10 Primary and secondary headache syndromes

**Primary headache syndromes**
- Migraine (with or without aura)
- Tension-type headache
- Trigeminal autonomic cephalalgia (including cluster headache)
- Primary stabbing/coughing/exertional/sex-related headache
- Thunderclap headache
- New daily persistent headache syndrome

**Secondary causes of headache**
- Medication overuse headache (chronic daily headache)
- Intracranial bleeding (subdural haematoma, subarachnoid or intracerebral haemorrhage)
- Raised intracranial pressure (brain tumour, idiopathic intracranial hypertension)
- Infection (meningitis, encephalitis, brain abscess)
- Inflammatory disease (temporal arthritis, other vasculitis, arthritis)
- Referred pain from other structures (orbit, temporomandibular joint, neck)

---

### 10.12 Identification of bacterial meningitis

In patients presenting with headache, identification of those with bacterial meningitis is a top priority to facilitate rapid antibiotic treatment. In almost all cases there will be one of the following features:
- Meningitis (neck stiffness, photophobia, positive Kernig’s sign)
- Fever >38°C
- Signs of shock (tachycardia, hypotension, elevated serum lactate)
- Rash (not always petechial)
after headache onset, to look for evidence of xanthochromia. It is increasingly accepted, however, that a negative CT scan within 6 hours of headache onset has such a high degree of sensitivity for excluding subarachnoid haemorrhage that an LP is not necessary. In such circumstances, a CT angiogram should be considered to exclude other pathology, such as arterial dissection. Many headaches require prompt involvement of specialists. Features of acute glaucoma, for example, require immediate ophthalmological review for measurement of intraocular pressures. Suspected temporal arteritis with an erythrocyte sedimentation rate (ESR) of >50 mm/hr should prompt immediate glucocorticoid therapy and rheumatological referral (see p. 1042 for management). Features of raised ICP in the absence of a mass lesion on neuroimaging may indicate idiopathic intracranial hypertension; CSF opening pressure is likely to be informative.

**Unilateral leg swelling**

Most leg swelling is caused by oedema, the accumulation of fluid within the interstitial space. There are three explanatory mechanisms for the development of oedema that may occur in isolation or combination:

- Increased hydrostatic pressure in the venous system due to increased intravascular volume or venous obstruction
- Decreased oncotic pressure secondary to a decrease in the plasma proteins that retain fluid within the circulation
- Obstruction to lymphatic drainage (‘lymphoedema’)

**Presentation**

Any patient who presents with unilateral leg swelling should be assessed with the possibility of deep vein thrombosis (DVT) in mind. The pain and swelling of a DVT is often fairly gradual in onset, over hours or even days. Sudden-onset pain in the posterior aspect of the leg is more consistent with gastrocnemius muscle tear (which may be traumatic or spontaneous) or a ruptured Baker’s cyst. Leg swelling and pain associated with paraesthesia or paresis, or in the context of lower limb injury or reduced conscious level, should always prompt concern regarding the possibility of compartment syndrome (Box 10.14).

**Clinical assessment**

Lower limb DVT characteristically starts in the distal veins, causing an increase in temperature of the limb and dilatation of the superficial veins. Often, however, symptoms and signs are minimal.

---

</tbody>
</table>

There are three explanatory mechanisms for the development of oedema that may occur in isolation or combination:

- Increased hydrostatic pressure in the venous system due to increased intravascular volume or venous obstruction
- Decreased oncotic pressure secondary to a decrease in the plasma proteins that retain fluid within the circulation
- Obstruction to lymphatic drainage (‘lymphoedema’)

---
Cellulitis is usually characterised by erythema and skin warmth localised to a well-demarcated area of the leg and may be associated with an obvious source of entry of infection (e.g. leg ulcer or insect bite). The patient may be febrile and systemically unwell. Superficial thrombophlebitis is more localised; erythema and tenderness occur along the course of a vein, palpable vein.

Examination of any patient presenting with leg swelling should include assessment for malignancy (evidence of weight loss, a palpable mass or lymphadenopathy), Malignancy is a risk factor for DVT, but pelvic or lower abdominal masses can also produce leg swelling by compressing the pelvic veins or lymphatics. Early lymphoedema is indistinguishable from other causes of oedema. More chronic lymphoedema is firm and non-pitting, often with thickening of the overlying skin, which may develop a ‘cobblestone’ appearance.

Chronic venous insufficiency is a cause of long-standing oedema that, particularly when combined with another cause of leg swelling, may acutely worsen. Characteristic skin changes (haemosiderin deposition, hair loss, varicose eczema, ulceration) and prominent varicosities are common, and sometimes cause diagnostic confusion with cellulitis. See Box 10.14 for the examination findings associated with compartment syndrome.

**Initial investigations**

Clinical criteria can be used to rank patients according to their likelihood of DVT, by using scoring systems based on the Wells score (Box 10.15). Figure 10.6 gives an algorithm for investigation of suspected DVT based on initial Wells score. In patients with a low (‘unlikely’) pre-test probability of DVT, D-dimer levels can be measured; if these are normal, further investigation for DVT is unnecessary. In those with a moderate or high (‘likely’) probability of DVT or with elevated D-dimer levels, objective diagnosis of DVT should be obtained using appropriate imaging, usually a Doppler ultrasound scan. The investigative pathway for DVT, therefore, differs according to the pre-test probability (p. 11) of DVT. For low-probability DVT, the negative predictive value of the D-dimer test (the most important parameter in this context) is over 99%; if the test is negative, the clinician can discharge the patient with confidence. In patients with a high probability of DVT, the negative predictive value of a D-dimer test falls to somewhere in the region of 97–98%. While this may initially appear to be a high figure, to discharge 2 or 3 patients in every 100 incorrectly would generally be considered an unacceptable error rate. Hence, with the exception of pregnancy (Box 10.16), a combination of clinical probability and blood test results should be used in the diagnosis of venous thromboembolism.

If cellulitis is suspected, serum inflammatory markers, skin swabs and blood cultures should be sent, ideally before antibiotics are given. Ruptured Baker’s cyst and calf muscle tear can both be readily diagnosed on ultrasound. If pelvic or lower abdominal malignancy is suspected, a prostate-specific antigen (PSA) level should be measured in males and appropriate imaging with ultrasound (transabdominal or transvaginal) or CT should be undertaken.
Identification and assessment of deterioration

Early warning scores and the role of the medical emergency team

There are many systems that have been developed with the aim of rapidly identifying and managing physiological deterioration. These are referred to as ‘rapid response systems’. One popular example of a rapid response system is a medical emergency team (MET). A MET system operates on the basis that when a patient meets certain physiological criteria, the team is alerted. The team is expected to make a rapid assessment and institute immediate management. This may include escalation to critical care or, following liaison with the parent clinical team, ongoing ward-based care.

The trigger for a ‘MET’ call may be a single parameter – such as a low BP or tachycardia – or may consist of a composite early warning score. Early warning score systems function by the observer allocating a value between 0 and 3 for abnormalities in respiratory rate, \( \text{SpO}_2 \), temperature, BP, heart rate, neurological response and urine output (Fig. 10.7). The values are summed and the composite score gives an indication of the severity of physiological derangement. Early warning systems can be automated into an electronic format that calculates the score and even alerts the responsible clinician(s) by email or text message.

There are advantages and disadvantages to having a separate MET system, compared with allowing the responsible clinical team to manage deterioration, and to having a composite score or a single parameter detection system. These are outlined in Box 10.17.

Immediate assessment of the deteriorating patient

An approach to assessment of the deteriorating patient can be summarised by the mnemonic ‘C-A-B-C-D-E’.

C – Control of obvious problem

For example, if the patient has ventricular tachycardia on the monitor or significant blood loss is apparent, immediate action is required.

A and B – Airway and breathing

If the patient is talking in full sentences, then the airway is clear and breathing is adequate. A rapid history should be obtained while the initial assessment is undertaken. Breathing should be assessed with a focused respiratory examination. Oxygen saturations and ABGs should be checked early (p. 190).
Identification and assessment of deterioration

- Inform registered nurse
- Registered nurse assessment using ABCDE
- Review frequency of observations
- Inform Nurse in Charge
- If ongoing concern, escalate to Medical Team

- Continue routine NEWS monitoring with every set of observations
  - Minimum 12 hourly/4 hourly in admission areas

- Consider Structured Response Tool
- Consider Fluid Balance Chart

- Increase frequency to a minimum of 1 hourly
  - Start Structured Response Tool
  - Start Fluid Balance Chart

- Continuous monitoring of vital signs
  - Start Structured Response Tool
  - Start Fluid Balance Chart

“Regardless of NEWS always escalate if concerned about a patient’s condition

(GCS = Glasgow Coma Scale; MET = Medical Emergency Team; MEWS = Modified Early Warning Score; NEWS = National Early Warning Score)

C – Circulation

A focused cardiovascular examination should include heart rate and rhythm, jugular venous pressure, evidence of bleeding, signs of shock and abnormal heart sounds. The carotid pulse should be palpated in the collapsed or unconscious patient, but peripheral pulses also should be checked in conscious patients. The radial, brachial, foot and femoral pulses may disappear as shock progresses, and this indicates the severity of circulatory compromise.

D – Disability

Conscious level should be assessed using the GCS (see Fig. 10.5 and Box 10.24, pp. 186 and 194). A brief neurological examination looking for focal signs should be performed. Capillary blood glucose should always be measured to exclude hypoglycaemia or severe hyperglycaemia.

E – Exposure and evidence

“Exposure” indicates the need for targeted clinical examination of the remaining body systems, particularly the abdomen and lower limbs. “Evidence” may be gathered via a collateral history from other health-care professionals or family members, recent investigations, prescriptions or monitoring charts.

**Selecting the appropriate location for ongoing management**

Any patient who will gain benefit from a critical care area should be admitted. Such patients generally fall into two groups: those with organ dysfunction severe enough to require organ support and those in whom the disease process is clearly setting them on a downward trajectory and in whom early, aggressive management may alter the outcome. Whether an individual patient should be
admitted to the intensive care or high-dependency unit (ICU/HDU) will depend on local arrangements. A useful tool to assist with the decision regarding location is the ‘level of care’ required (Box 10.18). Many intensive care units are a mix of level 2 and level 3 beds, which streamlines the admission process.

### Common presentations of deterioration

As patients become critically unwell, they usually manifest physiological derangement. The principle underpinning critical care is the simultaneous assessment of illness severity and the stabilisation of life-threatening physiological abnormalities. The goal is to prevent deterioration and effect improvements, as the diagnosis is established and treatment of the underlying disease process is initiated.

It can be useful to consider the physiological changes as a starting point to help delineate urgent investigations and supportive treatment, which should proceed alongside the search for a definitive diagnosis.

### Tachypnoea

**Pathophysiology**

A raised respiratory rate (tachypnoea) is the earliest and most sensitive sign of clinical deterioration. Tachypnoea may be primary (i.e. a problem within the respiratory system) or secondary to pathology elsewhere in the body. Cardiopulmonary causes of tachypnoea have been covered on page 179. Secondary tachypnoea is usually due to a metabolic acidosis, most commonly observed in the context of sepsis, haemorrhage, ketoacidosis or visceral ischaemia. More detailed information on metabolic acidosis can be found on page 364.

**Assessment and management**

A simple assessment of a patient’s clinical status and basic physiology will usually indicate whether urgent intervention is required. In the examination, attention should be paid to the adequacy of chest expansion, air entry and the presence of added sounds such as wheeze.

Analysis of an arterial blood sample is especially helpful in narrowing the differential diagnosis and confirming clinical suspicion of severity. The ‘base excess’ provides rapid quantification of the component of disease that is metabolic in origin. A base excess lower than −2 mEq/L (or, put another way, a ‘base deficit’ of more than 2 mEq/L) is likely to represent a metabolic acidosis. A simple rule of thumb is that a lactate of more than 4 mmol/L or a base deficit of more than 10 mEq/L should cause concern and trigger escalation to a higher level of care. In addition to clinical examination, chest radiography and bedside ultrasound can help to distinguish the cause of poor air entry; consolidation and effusion can be readily identified and a significant pneumothorax can be excluded (as shown in Fig. 10.8).

### Hypoxaemia

**Pathophysiology**

Low arterial partial pressure of oxygen (PaO₂) is termed hypoxaemia. It is a common presenting feature of deterioration. Hypoxia is defined as an inadequate amount of oxygen in tissues (or the inability of cells to use the available oxygen for cellular respiration). Hypoxia may be due to hypoxaemia, or may be secondary to impaired cardiac output, the presence of inadequate or dysfunctional haemoglobin, or intracellular dysfunction (such as in cyanide poisoning, where oxygen utilisation at the cellular level is impaired).

Over 97% of oxygen carried in the blood is bound to haemoglobin. The haemoglobin–oxygen dissociation curve delineates the relationship between the percentage saturation of haemoglobin with oxygen (SO₂) and the partial pressure (PO₂) of oxygen in the blood. A shift in the curve will influence the uptake and release of oxygen by the haemoglobin molecule. As capillary PCO₂ rises, the curve moves to the right, increasing the offloading of oxygen in the tissues (the Bohr effect). This increases capillary PO₂ and hence cellular oxygen supply. Shifts of the oxyhaemoglobin dissociation curve can have significant implications in certain disease processes (Fig. 10.9).
Common presentations of deterioration

• 191

with acute stroke, those with MI and those who chronically retain CO₂. Adverse effects of hyperoxia include:
• free radical-induced tissue damage
• less efficient buffering of carbon dioxide by oxyhaemoglobin (compared to deoxyhaemoglobin)
• less efficient ventilation–perfusion matching in lung units (due to loss of hypoxic vasoconstriction of under-ventilated lung units)
• decreased hypoxic respiratory drive in individuals with chronic hypercapnia.

When attempting to determine the cause of hypoxaemia, it is useful to consider whether the primary physiological mechanism is a type of shunt, or one of the many causes of ventilation–perfusion mismatch, such as alveolar or central hypoventilation (Fig. 10.10). A classification of common causes of hypoxaemia in hospitalised patients is shown in Box 10.20. In reality, the observed physiological abnormality may represent a combination of inter-related processes, such as severe pulmonary oedema leading to exhaustion, which in turn causes hypoventilation.

Evaluation of risk factors, history and examination will help to differentiate the likely aetiology and guide specific management. Further management of respiratory failure is discussed on page 202.

10.19 Prescribing oxygen in critical illness

• Oxygen should be prescribed to achieve a target saturation of 94–98% for most critically unwell patients.
• 88–92% is a more appropriate target range for those at risk of hypercapnic respiratory failure.

With acute stroke, those with MI and those who chronically retain CO₂. Adverse effects of hyperoxia include:
• free radical-induced tissue damage
• less efficient buffering of carbon dioxide by oxyhaemoglobin (compared to deoxyhaemoglobin)
• less efficient ventilation–perfusion matching in lung units (due to loss of hypoxic vasoconstriction of under-ventilated lung units)
• decreased hypoxic respiratory drive in individuals with chronic hypercapnia.

When attempting to determine the cause of hypoxaemia, it is useful to consider whether the primary physiological mechanism is a type of shunt, or one of the many causes of ventilation–perfusion mismatch, such as alveolar or central hypoventilation (Fig. 10.10). A classification of common causes of hypoxaemia in hospitalised patients is shown in Box 10.20. In reality, the observed physiological abnormality may represent a combination of inter-related processes, such as severe pulmonary oedema leading to exhaustion, which in turn causes hypoventilation.

Evaluation of risk factors, history and examination will help to differentiate the likely aetiology and guide specific management. Further management of respiratory failure is discussed on page 202.

Tachycardia

Pathophysiology

A heart rate of >110 beats/min in an adult should always be considered abnormal and not attributed to anxiety until other causes have been excluded. Intrinsic cardiac causes (atrial fibrillation (AF), atrial flutter, supraventricular tachycardia and
Hypovolaemia should not be missed. Concealed bleeding (e.g. into the pleura, gastrointestinal tract or retroperitoneum) may not be apparent initially and assessment of haemoglobin in an acute haemorrhage, when < 30 mL/kg of fluid has been administered, can be misleadingly high. Sepsis and other hyper-metabolic conditions may present with a tachycardia that is accompanied by tachypnoea, peripheral vasodilatation and a raised temperature. Other organ dysfunction should be noted from a brief general examination and salient points from the history.

Assessment and management

The management of a tachycardic patient should focus on treating the cause. Treating the rate alone with beta-blockade in an unwell or deteriorating patient should be done only under specialist guidance, in controlled conditions, and when a clear evaluation of the risk–benefit ratio has been undertaken.

The recognition and management of primary cardiac dysrhythmias are discussed on page 468. The most appropriate method of rate control in AF depends primarily on the degree of haemodynamic compromise. An intravenous loading dose of amiodarone is well tolerated and efficacious in the majority of critically ill patients with AF and a very rapid ventricular rate. There are thromboembolic concerns regarding chemical cardioversion of AF of unknown duration. However, in deteriorating patients, the low incidence of embolic events makes this concern of secondary importance to achieving haemodynamic stability. Digoxin continues to have a role in the treatment of AF in critically unwell but haemodynamically stable patients, when ventricular dysrhythmias) are less common in the general inpatient population than secondary causes of tachycardia.

A cardiac monitor or 12-lead ECG early in the examination will help both determine severity (heart rate > 160 beats/min should prompt urgent escalation to a higher level of care) and narrow the differential diagnosis. AF with a rapid ventricular response should usually be regarded as secondary to another insult (mostly commonly, infection) until other diagnoses have been excluded.

**Fig. 10.10 Theoretical mechanisms of hypoxaemia.**

- **A** Normal physiology.
- **B** Shunt caused by alveolar filling, e.g. in pneumonia or alveolar haemorrhage. The mixture of oxygenated and deoxygenated blood causes arterial desaturation.
- **C** Shunt caused by interstitial pathology, e.g. pulmonary oedema or fibrosis. Interstitial thickening causes inadequate transfer of oxygen from the alveolus to the blood, leading to shunting and arterial desaturation. Because minute volume is usually maintained, this causes type I respiratory failure.
- **D** Ventilation–perfusion (V/Q) mismatch caused by alveolar hypoventilation, e.g. in chronic obstructive pulmonary disease (COPD)/asthma. Alveoli are under-ventilated relative to perfusion. Alveolar PO\(_2\) falls and PCO\(_2\) rises, causing type II respiratory failure.
- **E** V/Q mismatch caused by central hypoventilation, e.g. in neuromuscular disease or narcotic use. The alveoli are relatively over-perfused, causing type II respiratory failure.
- **F** V/Q mismatch caused by a perfusion defect, e.g. a small pulmonary embolism. Pulmonary blood flow is diverted to other alveoli, causing them to be relatively over-perfused and thus reducing alveolar PO\(_2\). Minute volume is increased, so PCO\(_2\) is not elevated.

---

**Table 10.20 Common causes of hypoxaemia in hospitalised patients**

**Hypoxaemia due to shunt**
- Lung collapse
- Consolidation/alveolar haemorrhage
- Interstitial oedema or interstitial infiltration (e.g. fibrosis)
- Silent aspiration of gastric contents

**Hypoxaemia due to ventilation–perfusion mismatch**
- Pulmonary embolism
- Acute exacerbation of asthma
- COPD (with high minute volume)

**Hypoxaemia from hypoventilation**
- Effects of opiates
- Severe COPD (with low minute volume)
- Neuromuscular disease/general weakness from other illness

(COPD = chronic obstructive pulmonary disease)
its inotropic properties can be helpful. Electrical cardioversion is reserved for dysrhythmias with extremely high heart rates, following failure of pharmacological management, and/or for those of ventricular origin. It is rarely successful in dysrhythmias secondary to systemic illness.

**Hypotension**

**Pathophysiology**

Low BP (hypotension) should always be defined in relation to a patient’s usual BP. The calculation of mean arterial pressure (MAP) is shown in Box 10.21; it unifies the systolic and diastolic BPs into a single reference value. A MAP of >65 mmHg will maintain renal perfusion in the majority of patients, although a MAP of up to 80 mmHg may be required in patients with chronic hypertension.

**Assessment and management**

The first stage of assessment is to decide if the hypotension is physiological or pathological. The MAP is useful as, despite low systolic pressures, it is rare to see a physiological MAP of <65 mmHg. Urine output is particularly useful in the determination of the desirable MAP for an individual patient; oliguria suggests that measures to increase the MAP should be sought (p. 204). If the hypotension is pathological, an assessment of severity should look at whether it is causing physiological harm to the patient (i.e. the patient is shocked).

**Shock**

Shock means ‘circulatory failure’. It can be defined as a level of hypotension that the patient is shocked. Should look at whether it is causing physiological harm to the patient (i.e. the patient is shocked).

**Calculation of mean arterial pressure (MAP)**

\[
\text{MAP} = \frac{\text{Diastolic blood pressure} + (\text{systolic} - \text{diastolic})}{3}
\]

At normal heart rates, the heart, on average, spends two-thirds of the cycle in diastole. The MAP reflects this by weighting the value towards the diastolic blood pressure.

**Oxygen content and delivery**

- Oxygen content of blood = "Haemoglobin level × oxygen saturation × constant"
- Cardiac output = Heart rate × stroke volume
- Stroke volume is dependent on cardiac filling (preload) and contractility
- In shock, the most productive measures to improve oxygen delivery are optimising the haemoglobin level and the cardiac output

*Oxygen is almost exclusively bound to haemoglobin; only tiny amounts are dissolved in blood at atmospheric pressure.*

Early identification. If shock is suspected, resuscitation should be commenced (p. 204).

Hypotensive patients who do not have any evidence of shock are still at significant risk of organ dysfunction. Hypotension should serve as a ‘red flag’ that there may be serious underlying pathology. Organ failure occurs despite normal or elevated oxygen delivery, so a full assessment of the patient is indicated. A review of the drug chart is essential, as many inpatients will be on antihypertensive medications that are contributing to hypotension. Non-cardiac medications may also have a negative influence on BP; for example, some drugs used for urine outflow tract obstruction, such as tamsulosin, have an α-adrenoceptor-blocking effect.

**Hypertension**

**Pathophysiology**

High BP (hypertension) is common and is usually benign in a critical care context. However, it can be the presenting feature of a number of serious disease processes. Furthermore, acute hypertension can result in an acute rise in vascular tone that increases left ventricular end-systolic pressure (afterload). The left ventricle may be unable to eject blood against the increased aortic pressure, and acute pulmonary oedema can result (referred to as ‘flash’ pulmonary oedema.)

**Assessment and management**

Before treating an acute rise in BP, it is worth considering a few important diagnoses that may impact on the immediate management:

- **Intracranial event.** Ischaemia of the brainstem (commonly via a pressure effect) will cause acute increases in BP. A neurological examination and CT scan of the head should be considered.
- **Fluid overload.** Once the capacity of the venous blood reservoir becomes saturated, increases in fluid volume will lead to increases in BP. This can occur in younger patients without the onset of peripheral oedema and originate from myocardial dysfunction or impaired renal clearance.
- **Underlying medical problems.** A brief search for a history of renal disease, spinal injury and less common metabolic causes such as phaeochromocytoma can be worthwhile. In women of child-bearing age, pregnancy-induced
hypertension and pre-eclampsia must always be considered.

- **Primary cardiac problems.** Myocardial ischaemia, acute heart failure and aortic dissection can all present with hypertension.
- **Drug-related problems.** Most commonly, these involve a missed antihypertensive medication, but sympathomimetic drugs such as cocaine and amphetamines can be implicated.

The management of hypertension is discussed further on page 510.

**Decreased conscious level**

**Assessment**

A reduction in conscious level should prompt an urgent assessment of the patient, a search for the likely cause and an evaluation of the risk of airway loss. The GCS was developed to risk-stratify head injury, but it has become the most widely recognised assessment tool for conscious level (see Box 10.24 for breakdown of GCS assessment, Box 10.25 for how to communicate the findings and Fig. 10.5 for how to assess GCS). While disorders that affect language or limb function (e.g. left hemisphere stroke, locked-in syndrome) may reduce its usefulness, evaluation of the GCS usually provides helpful prognostic information, and serial recordings can plot improvement or deterioration. It is not possible to define a total score below its usefulness, evaluation of the GCS usually provides helpful prognostic information, and serial recordings can plot improvement or deterioration.

A reduction in conscious level should prompt an urgent search for the likely cause and an evaluation of the risk of airway loss. The GCS was developed to risk-stratify head injury, but it has become the most widely recognised assessment tool for conscious level (see Box 10.24 for breakdown of GCS assessment, Box 10.25 for how to communicate the findings and Fig. 10.5 for how to assess GCS). While disorders that affect language or limb function (e.g. left hemisphere stroke, locked-in syndrome) may reduce its usefulness, evaluation of the GCS usually provides helpful prognostic information, and serial recordings can plot improvement or deterioration. **Coma score = E + M + V**

Always present GCS as breakdown, not a sum score (unless 3 or 15)

- Minimum sum 3
- Maximum sum 15

*Record the best score observed. When the patient is intubated, there can be no verbal response. The suffix ‘T’ should replace the verbal component of the score, and the remainder of the score is therefore a maximum of 10.*

Coma is defined as a persisting state of deep unconsciousness. In practice, this means a sustained GCS of 8 or less. There are many causes of coma (Box 10.26), including neurological (structural or non-structural brain disease) and non-neurological (e.g. type II respiratory failure) ones. The mode of onset of coma and any precipitating event is crucial to establishing the cause, and should be obtained from witnesses. Failure to obtain an adequate history for patients in coma is a common cause of diagnostic delay.

Once the patient is stable from a cardiorespiratory perspective, examination should include accurate assessment of conscious level and a thorough general medical examination, looking for clues such as needle tracks indicating drug abuse, rashes, fever and focal signs of infection, including neck stiffness or evidence of head injury. Focal neurological signs may suggest a structural explanation (stroke or tumour) or may be falsely localising (for example, 6th nerve palsy can occur as a consequence of raised intracerebral pressure). It is vital to exclude non-neurological causes of coma. Sodium and glucose should be measured urgently as part of the initial assessment, as acute hyponatraemia (p. 358) and hypoglycaemia (p. 738) are easily corrected and can cause irreversible brain injury if missed.

**Causes of coma**

- **Metabolic disturbance**
  - Drug overdose
  - Diabetes mellitus: Hypoglycaemia
  - Ketoacidosis
  - Hyperosmolar coma
  - Hyponatraemia
  - Uraemia
  - Hepatic failure (hyperammonaemia)
  - Inborn errors of metabolism causing hyperammonaemia
  - Hyperammonaemia on refeeding following profound anorexia
  - Respiratory failure
  - Hypothermia
  - Hypothyroidism

- **Trauma**
  - Cerebral contusion
  - Extracranial haematoma
  - Subdural haematoma
  - Diffuse axonal injury

- **Vascular disease**
  - Subarachnoid haemorrhage
  - Brainstem infarction/haemorrhage
  - Intracerebral haemorrhage
  - Cerebral venous sinus thrombosis

- **Infections**
  - Meningitis
  - Encephalitis
  - Cerebral abscess
  - Systemic sepsis

- **Others**
  - Epilepsy
  - Brain tumour
  - Functional (‘pseudo-coma’)
Non-contrast CT of the head showing CT angiogram of the circle of Willis demonstrating dysfunction. Therefore, early intubation and the prevention of lung injury constitute the safer option if there is any doubt about a patient’s ability to protect the airway from obstruction or aspiration.

**Decreased urine output/deteriorating renal function**

**Assessment**

A urine output of 0.5 mL/kg/hr is a commonly quoted, though admittedly arbitrary target. Although some patients can produce urine volumes below this level with no change in their renal biochemistry, such low volumes should alert the clinician to the possibility of suboptimal renal perfusion.

Oliguria in association with hypotension or an increase in serum creatinine level (even if small) should prompt examination for the underlying cause. Pre-renal causes predominate in the general inpatient population, so optimising the MAP by administration of intravenous fluids (and possibly vasoressors) is the first priority. In the majority of inpatients there is no role for high volumes (i.e. >30 mL/kg) of intravenous fluid if the MAP is normal. Exceptions to this rule include patients with clinical dehydration or high fluid losses such as in burns, diabetes emergencies (pp. 735 and 738) and diabetes insipidus (p. 887), where fluid management should be guided by local protocols.

**Diagnosis and management**

Further assessment and management of oliguria are explained on page 391. Two other important causes of renal failure in the inpatient population are abdominal compartment syndrome and rhabdomyolysis.

**Abdominal compartment syndrome**

Abdominal compartment syndrome occurs when raised pressure within the abdomen reduces perfusion to the abdominal organs. It is most commonly seen in surgical patients, but can occur in medical conditions with extreme fluid retention such as liver cirrhosis. When it is suspected, intra-abdominal pressure can be monitored via a pressure transducer connected to a urinary catheter (following instillation of 25 mL of 0.9% saline into the bladder). Values over 20 mmHg suggest abdominal compartment syndrome is present. Urgent measures should be taken to reduce the pressure, such as decompression of the stomach, bladder and peritoneum if ascites is present. If conservative measures fail, a laparostomy should be considered.

**Rhabdomyolysis**

Rhabdomyolysis occurs when there is an injury to a large volume of skeletal muscle, usually because a single limb or muscle compartment has been ischaemic for a prolonged period. It can also occur following trauma and crush injury or after over-exertion of muscles. Over-exertion can occur after intense physical exercise or as part of a medical condition that causes widespread muscular activity, such as malignant hyperpyrexia or neuroleptic malignant syndrome. A creatine kinase (CK) level of >1000 U/L is highly suggestive, although it can rise to tens of thousands in severe cases. Management should focus on identification and correction of the underlying cause and support for multi-organ dysfunction. Forced alkaline diuresis (using intravenous bicarbonate infusion and furosemide) can be used to maintain a good flow of less acidic fluid within the renal tubules and reduce myoglobin precipitation.

Further investigations should be guided by the clinical presentation and examination findings; a sudden onset suggests a vascular cause. An early CT scan of the brain may demonstrate any gross pathology but if a brainstorm stroke is suspected (Fig. 10.11), a CT angiogram of the circle of Willis will provide more useful information, as a non-contrast CT is frequently negative in this context. If there are features suggestive of cerebral venous thrombosis, such as thrombophilia or sinus infection, a CT venogram should be performed. Meningitis or encephalitis may be suggested by the history, signs of infection or subtle radiological findings. If these diagnoses are considered, it is best to commence treatment with broad-spectrum antibiotics and antivirals while awaiting more definitive diagnostic information.

Other drug, metabolic and hepatic causes of reduced conscious level are dealt with in the relevant chapters. An ammonia level (sent on ice) can narrow the differential diagnosis to a metabolic or hepatic cause if there is diagnostic doubt; levels >100 μmol/L (140 μg/dL) are significantly abnormal. Psychiatric conditions such as catatonic depression or neurological conditions such as the autoimmune encephalitides can cause a reduced level of consciousness, but they are diagnoses of exclusion and will require specialist input.

**Management**

Moving an unconscious patient into the recovery position is best for airway protection while preparations are made for escalation to a higher level of care. The decision regarding intubation for airway protection is always difficult. Length of stay in intensive care is significantly reduced if there is no secondary organ dysfunction. Therefore, early intubation and the prevention of lung injury constitute the safer option if there is any doubt about a patient’s ability to protect the airway from obstruction or aspiration.

**Fig. 10.11** Hyperacute changes in conscious state are commonly of vascular origin. CT of the brain is unlikely to identify many vascular causes but a CT angiogram of the circle of Willis is a high-yield investigation in this context. A Non-contrast CT of the head showing hyperdense thrombus in the basilar artery (arrow). This is a specific, but not sensitive, sign. B CT angiogram of the circle of Willis demonstrating thrombosis in the basilar artery (arrow). This has better sensitivity for acute vascular occlusion.
**Disorders causing critical illness**

**Sepsis and the systemic inflammatory response**

Sepsis is one of the most common causes of multi-organ failure. Sepsis requires the presence of infection with a resultant systemic inflammatory state; organ dysfunction occurs from a combination of the two processes. The definition of sepsis has undergone various iterations and there is still a lack of consensus as to the exact wording that best reflects this complex, multisystem process (Box 10.27).

**Aetiology and pathogenesis**

To understand how an infection can lead to progressive multi-organ failure, it is essential to have a grasp of the pathophysiology.

**Initiation of the inflammatory response**

The process begins with infection in one part of the body that triggers a localised inflammatory response. Appropriate source control and a competent immune system will, in most cases, contain the infection at this stage. However, if certain factors are present, the infection may become systemic. The causative factors are not fully elucidated but probably include:

- A genetic predisposition to sepsis
- A large microbiological load
- High virulence of the organism
- Delay in source control (either surgical or antimicrobial)
- Resistance of the organism to treatment
- Patient factors (immune status, nutrition, frailty).

Mediators are released from damaged cells (called ‘alarmins’) and these, coupled with direct stimulation of immune cells by the molecular patterns of the microorganism, trigger the inflammatory response. An example of such direct stimulation is that of lipopolysaccharide, which is found on the surface of Gram-negative bacteria. It strongly stimulates an immune response. The exact wording that best reflects this complex, multisystem process is (Box 10.27).

**Definitions of sepsis and septic shock**

<table>
<thead>
<tr>
<th>Sepsis</th>
<th>Septic shock</th>

<tr>
<td>Tachypnoea – respiratory rate ≥ 22 breaths/min</td>
<td>2. Serum lactate &gt; 2 mmol/L (18 mg/dL)</td>
</tr>
</tbody>
</table>

*From the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3).*

Hyperlactataemia (serum lactate ≥ 2 mmol/L or 22 mg/dL) is used as a marker of severity. Figure 10.13 explains the physiology of hyperlactataemia; it is caused by all types of shock and therefore is not specific to sepsis. A lactate level of > 8 mmol/L (73 mg/dL) is associated with an extremely high mortality and should trigger immediate escalation. Measures to optimise oxygen delivery should be sought, and the adequacy of resuscitation measured by lactate clearance.

**Propagation of the inflammatory response**

Once activated, immune cells such as macrophages release the inflammatory cytokines interleukin-2 (IL-2), IL-6 and tumour necrosis factor alpha, which, in turn, activate neutrophils. Activated neutrophils express adhesion factors and release various other inflammatory and toxic substances; the net effects are vasodilatation (via activation of inducible nitric oxide synthase enzymes) and damage to the endothelium. Neutrophils migrate into the interstitial space; fluid and plasma proteins will also leak through the damaged endothelium, leading to oedema and intravascular fluid depletion.

**Activation of the coagulation system**

Damaged endothelium triggers the coagulation cascade (via tissue factor, factor VII, and reduced activity of proteins C and S) and thrombus forms within the microvasculature. A vicious circle of endothelial injury, intravascular coagulation and microvascular occlusion develops, causing more tissue damage and further release of inflammatory mediators. In severe sepsis, intravascular coagulation can become widespread. This is referred to as disseminated intravascular coagulation (DIC) and usually heralds the onset of multi-organ failure. Specific aspects of the diagnosis and management of DIC are discussed on page 978.

**Organ damage from sepsis**

Any and all organs may be injured by severe sepsis. The pathological mechanisms are shown in Figure 10.12.

**Lactate physiology**

Lactate is an excellent biomarker for the severity of sepsis. Hyperlactataemia (serum lactate > 2.4 mmol/L or 22 mg/dL) is used as a marker of severity. Figure 10.13 explains the physiology of hyperlactataemia; it is caused by all types of shock and therefore is not specific to sepsis. A lactate level of > 8 mmol/L (> 73 mg/dL) is associated with an extremely high mortality and should trigger immediate escalation. Measures to optimise oxygen delivery should be sought, and the adequacy of resuscitation measured by lactate clearance.

**The anti-inflammatory cascade**

As the inflammatory state develops, a compensatory anti-inflammatory system is activated involving the release of anti-inflammatory cytokines such as IL-4 and IL-10 from immune cells. While such mechanisms are necessary to keep the inflammatory response in check, they may lead to a period of immunosuppression after the initial septic episode. Patients recovering from severe sepsis are prone to developing secondary infections due to a combination of this immunosuppression and the presence of indwelling devices.

**Management**

The most important action is to consider sepsis as the cause of a patient’s deterioration. Aligned to this is the requirement to consider other diagnoses that could be causing the presentation, such as haemorrhage, PE, anaphylaxis or a low cardiac output state.

**Resuscitation in sepsis**

General resuscitative measures are discussed on page 204. Early resuscitation can be aided by following the requirements of the
Disorders causing critical illness

• 197 crystalloid. Early intubation is recommended in severe cases to facilitate further management and reduce oxygen demand.

Appropriate antibiotics should be administered as early as possible (Box 10.29). The antibiotic choice will depend on local patterns of resistance, patient risk factors and the likely source of infection. Information on likely organisms and appropriate antibiotics can be found on pages 117 and 226. Microbiological samples (such as blood cultures, urine or CSF) should be taken, but this should not delay antibiotic administration, if obtaining samples is difficult.

Early source control

Source control requires an accurate diagnosis; urgent investigations should be performed as soon as physiological stability has been established. A CT scan of the chest and abdomen with contrast is a high-yield test in this context. Specific points in the history should be reviewed, such as risk factors for human immunodeficiency virus (HIV), contacts with tuberculosis and underlying immune status. Immunocompromised patients will be susceptible to a far broader spectrum of infectious microorganisms (p. 223).

10.28 The 'Sepsis Six'

1. Deliver high-flow oxygen
2. Take blood cultures
3. Administer intravenous antibiotics
4. Measure serum lactate and send full blood count
5. Start intravenous fluid replacement
6. Commence accurate measurement of urine output

*International recommendations for the immediate management of suspected sepsis from the Surviving Sepsis Campaign (all to be delivered within 1 hr of the initial diagnosis of sepsis).

10.29 Early administration of antibiotics in suspected sepsis

• Broad-spectrum antibiotics should be administered as soon as possible after sepsis is suspected
• Every hour of delayed treatment is associated with a 5–10% increase in mortality

Fig. 10.12 Pathophysiology of organ damage in sepsis. Macrovascular. Severe hypovolaemia, vasodilatation or septic cardiomyopathy can reduce oxygen delivery, causing tissue hypoxia. Paradoxically, most patients with sepsis have an increased cardiac output and oxygen delivery. Microvascular. Tissue injury can occur from hypoxia secondary to microvascular injury and thrombosis. Damaged epithelium permits neutrophils, proteins and fluid to leak out. Shunting. Organs fail in sepsis despite supranormal blood flow. It is likely that arteriovenous shunt pathways exist within vascular beds; these shunts open up in septic shock. Cellular. Cells are damaged by a number of mechanisms in sepsis: (1) direct injury by microorganisms; (2) injury from toxins produced by immune cells, e.g. oxygen free radicals; (3) mitochondrial injury causing cytopathic hypoxia – cells are unable to metabolise oxygen; (4) apoptosis – if the cell injury is sufficient, caspase enzymes are activated within the nucleus and programmed cell death occurs; (5) hypoxia from micro- and macrovascular pathology.

Fig. 10.13 Physiology of hyperlactataemia.

Inadequate oxygen delivery
Tissue hypoxia e.g. Ischaemic gut
Shock (from any cause)
Drugs e.g. Adrenaline (epinephrine) Salbutamol
Excess muscle activity e.g. Extreme exercise Seizure
Other causes: Metformin
Thiamin deficiency
Haematological malignancy
Drugs, e.g. antiretrovirals

Excess production

Anaerobic metabolism
β2-adrenoceptor stimulation
Excess tissue production

Inadequate clearance
Hepatic failure

High lactate

Congenital enzyme deficiencies (rare)
Noradrenaline (norepinephrine) for refractory hypotension

Central venous access should be established early in the resuscitation process and a noradrenaline infusion commenced. If there is severe hypotension, it is not necessary to wait until 30 mL/kg of fluid has been administered before commencing noradrenaline; early vasopressor use may improve the outcome from acute kidney injury. Measurement of central and mixed venous oxygen saturations may provide additional prognostic information (Box 10.30).

Other therapies for refractory hypotension

Refractory hypotension is due to either inadequate cardiac output or inadequate systemic vascular resistance (vasoplegia). When vasoplegia is suspected, it may be necessary to add vasopressin (antidiuretic hormone, ADH). This is a potent vasoconstrictor that may be used to augment noradrenaline (norepinephrine) in achieving an acceptable MAP. Intravenous glucocorticoids are also commonly used in refractory hypotension. There is little evidence that they improve the overall outcome, but they do lead to a more rapid reversal of the shocked state. There is a small increased risk of secondary infection following glucocorticoid use.

Septic cardiomyopathy

The myocardium can be affected by the septic process, presenting as either acute left or right ventricular dysfunction. A bedside echocardiogram is particularly useful to confirm the diagnosis, as ECG changes are usually non-specific. Dobutamine or adrenaline (epinephrine) can be used to augment cardiac output, and intravenous calcium should be replaced if ionised calcium is low.

Other interventions such as intravenous bicarbonate in profound metabolic acidosis, high-volume haemofiltration/haemodialysis and extracorporeal support are sometimes used, but currently lack evidence of benefit.

Review of the underlying pathology

While sepsis is the most common cause of acute systemic inflammation, up to 20% of patients initially treated for sepsis will have a non-infectious cause: that is, a sepsis mimic (Box 10.31). These conditions should be considered where the clinical picture is not typical, no source of sepsis can be found, or the inflammatory response seems excessive in the context of local infection. Early reconsideration of the diagnosis of sepsis is crucial, as many of the ‘sepsis mimics’ offer a finite time window for specific intervention, after which irreversible organ damage will have occurred.

### Acute respiratory distress syndrome

**Aetiology and pathogenesis**

Acute respiratory distress syndrome (ARDS) is a diffuse neutrophilic alveolitis caused by a range of conditions and characterised by bilateral radiographic infiltrates and hypoxaemia (Box 10.32). Activated neutrophils are sequestered into the lungs and capillary permeability is increased, with damage to cells within the alveoli. The pathophysiology is part of the inflammatory spectrum described in ‘Sepsis’ above, and the triggers are similar: infective and non-infective inflammatory processes. These processes result in exudation and accumulation of protein-rich cellular fluid within alveoli and the formation of characteristic ‘hyaline membranes’. Local release of cytokines and chemokines by activated macrophages and neutrophils results in progressive recruitment of inflammatory cells. Secondary effects include loss of surfactant and impaired surfactant production. The net effect is alveolar collapse and reduced lung compliance, most marked in dependent regions of the lung (mainly dorsal in supine patients). The affected airspaces become fluid-filled and can no longer contribute to ventilation, resulting in hypoxaemia (due to increased pulmonary shunt) and hypercapnia (due to inadequate ventilation in some areas of the lung): that is, ventilation-perfusion mismatch.

**Diagnosis and management**

ARDS can be difficult to distinguish from fluid overload or cardiac failure. Classic chest X-ray and CT appearances are shown in Figures 10.14 and 10.15, respectively. Occasionally, conditions may present in a similar way to ARDS but respond to alternative treatments; an example of this might be a glucocorticoid-responsive interstitial pneumonia (p. 605). Management of ARDS is supportive, including use of lung-protective mechanical ventilation, inducing a negative fluid balance and treating the underlying cause. Establishing the severity of ARDS (Box 10.33) is useful, as severe disease will require more proactive management such as prone positioning or extracorporeal membrane oxygenation (ECMO; p. 204).

### Central and mixed venous oxygen saturations

- Saturation of venous blood sampled from the right atrium or superior vena cava (central) or pulmonary artery (mixed venous)
- Both values reflect the balance of supply and demand of oxygen to the tissues
- Mixed venous oxygen saturation is a measure of whole-body supply and demand of oxygen; central venous oxygen saturation measures the supply and demand of oxygen from the upper body. Normal mixed venous oxygen saturation is 70%. Lower values than this suggest inadequate oxygen delivery
- Central venous oxygen saturation is more variable, depending on whether the patient is awake or anaesthetised, but a value of 70% is considered normal
- Where cytopathic hypoxia occurs, oxygen extraction is impaired and the central and mixed venous oxygen saturations may be >80%

### Berlin definition of ARDS

- Onset within 1 week of a known clinical insult, or new or worsening respiratory symptoms
- Bilateral opacities on chest X-ray, not fully explained by effusions, lobar/lung collapse or nodules
- Respiratory failure not fully explained by cardiac failure or fluid overload. Objective assessment (e.g. by echocardiography) must exclude hydrostatic oedema if no risk factor is present
- Impaired oxygenation (see Box 10.33)
Disorders causing critical illness

• 199

Infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the ‘downward spiral’ of cardiogenic shock (Fig. 10.17). Hypotension, oliguria, delirium and cold, clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness, hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. If necessary, a Swan–Ganz catheter can be used to measure the pulmonary artery pressures and cardiac output (p. 206). These findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 10.34) and titrate therapy accordingly.

In cardiogenic shock associated with acute MI, immediate percutaneous coronary intervention should be performed (p. 491). The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure

10.33 Determining the severity of ARDS

Severity of hypoxaemia is calculated using a Pa/FiO$_2$ ratio. This is a number calculated by using the PaO$_2$ from an arterial blood gas measurement divided by the fraction of inspired oxygen (FiO$_2$, expressed as a fraction).

For example, a patient with a PaO$_2$ of 10 kPa (75 mmHg) on 50% oxygen, i.e. FiO$_2$ of 0.5, would have a Pa/FiO$_2$ ratio of 20 kPa (150 mmHg). This would be defined as moderately severe ARDS, if the other Berlin criteria were met (see Box 10.32). All measurements should be taken on a minimum of 5 cmH$_2$O of PEEP or CPAP.

- Mild: 40–26.6 kPa (300–200 mmHg)
- Moderate: 26.6–13.3 kPa (200–100 mmHg)
- Severe: ≤ 13.3 kPa (≤ 100 mmHg)

(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)

Acute circulatory failure (cardiogenic shock)

**Definition and aetiology**

Cardiogenic shock is defined as hypoperfusion due to inadequate cardiac output or, more technically, a cardiac index of <2.2 L/min/m$^2$ (see Box 10.42). While cardiogenic shock is the final common pathway of many disease processes (e.g. sepsis, anaphylaxis, haemorrhage), the important primary causes of acute heart failure or cardiogenic shock (Fig. 10.16) are described here.

**Myocardial infarction**

In the majority of cases, cardiogenic shock following acute MI is due to left ventricular dysfunction. However, it may also be due to infarction of the right ventricle, or a variety of mechanical complications, including tamponade (due to infarction and rupture of the free wall), an acquired ventricular septal defect (due to infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the ‘downward spiral’ of cardiogenic shock (Fig. 10.17). Hypotension, oliguria, delirium and cold, clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness, hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. If necessary, a Swan–Ganz catheter can be used to measure the pulmonary artery pressures and cardiac output (p. 206). These findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 10.34) and titrate therapy accordingly.

In cardiogenic shock associated with acute MI, immediate percutaneous coronary intervention should be performed (p. 491). The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure
should be treated intensively because overall cardiac function may subsequently improve.

**Acute massive pulmonary embolism**
Massive PE may complicate leg or pelvic vein thrombosis and usually presents with sudden collapse. The clinical features and treatment are discussed on page 619. Bedside echocardiography may demonstrate a small, under-filled, vigorous left ventricle with a dilated right ventricle; it is sometimes possible to see thrombus in the right ventricular outflow tract or main pulmonary artery. In practice, it can be difficult to distinguish massive PE from a right ventricular infarct on transthoracic echocardiogram. CT pulmonary angiography usually provides a definitive diagnosis.

**Acute valvular pathology, aortic dissection and cardiac tamponade**
These conditions should be considered in an undifferentiated presentation of shock. The diagnosis and management of these conditions is discussed on pages 514, 506 and 544.

**Post cardiac arrest**
The initial management of cardiac arrest is discussed on page 456. Following the return of spontaneous circulation (ROSC), the majority of cardiac arrest survivors will need a period of time in intensive care to achieve physiological stability, identify...
and manage the underlying cause of the arrest, and optimise neurological recovery.

**Acute management**

A MAP of >70 mmHg should be maintained to optimise cerebral perfusion. Shock is common following ROSC and is caused by a combination of the underlying condition leading to the arrest, myocardial stunning and a post-arrest vasodilated state. Support with inotropes, vasopressors and occasionally mechanical support from an intra-aortic balloon pump or venous–arterial ECMO (p. 207) may be required. Specific cardiac interventions and their indications are described in Chapter 16. Other physiological targets are listed in Box 10.35.

**Prognosis**

Predicting which patients will not recover from the brain injury sustained at the time of cardiac arrest is very difficult. Certain features suggest that the outcome will be poor; for example, the absence of pupillary and corneal reflexes, absence of a motor response and persistent myoclonic jerking.

Tools to assist prognostication following cardiac arrest are shown in Box 10.36. The clinician should, where feasible, delay prognostication until a period of 72 hours of targeted temperature management has been completed. The bilateral absence of the ‘N20’ spike on the somato-sensory evoked potential is the most specific test to predict irrecoverable brain injury. This test is performed by administering an electrical impulse over a peripheral nerve and recording the electrical impulses measured by the scalp electrodes overlying the part of the brain expected to receive the impulse. Where this is not available, prognostication based on all other available information, along with the perceived wishes relating to the level of disability the individual would be prepared to accept, should allow a decision regarding ongoing treatment to be made. Where there is doubt, more time should be given to allow assessment of neurological recovery.

**Other causes of multi-organ failure**

As previously discussed, sepsis is the most common cause of multi-organ failure. However, multi-organ failure secondary to single organ dysfunction, such as cardiac failure, liver failure, renal failure or respiratory failure, is also common. The multisystem insult in these disease processes goes beyond the direct biochemical damage and tissue hypoxia caused by the primary organ dysfunction. It probably reflects cellular signalling pathways and the release of other systemic toxins by the failing organ, referred to as organ ‘crosstalk’.

Multi-organ failure can also be caused by a physiological insult that damages a wide variety of cells in different organs, including toxins from extrinsic sources such as envenomation and intrinsic sources such as myoglobin in rhabdomyolysis (p. 195). Multi-organ failure can also be caused by profound physical injury to cells from processes such as nuclear radiation, heat exposure or blast trauma.

---

### Box 10.35 Physiological targets following a return of spontaneous circulation (ROSC)

- **Temperature management.** Facilitate maintenance of temperature at 36°C and avoidance of pyrexia by the use of a cooling blanket. This should be continued for 72 hrs. Muscle relaxants may be required to prevent shivering.
- **Blood pressure management.** Aim for a MAP of at least 70 mmHg and a systolic blood pressure of >120 mmHg.
- **Glucose control.** Control the glucose to 6–10 mmol/L (108–180 mg/dL).
- **Normal CO₂ (4.5–6 kPa, 33–45 mmHg) and oxygen saturation (94–98%).** Avoid both hypoxaemia and hyperoxia.

### Box 10.36 Prognostication after cardiac arrest: predictors of poor neurological recovery

**Coexisting problems**

- Multi-organ failure
- Significant comorbidities

**Clinical**

- Persisting and generalised myoclonus
- Absence of pupillary or corneal reflexes
- Poor motor response (absent or extensor response)

**Biochemical**

- A neuron-specific enolase >33 µg/L

**Imaging**

- CT showing loss of grey–white differentiation
- Focal cause or consequence of cardiac arrest, e.g. subarachnoid haemorrhage

**Electrophysiology**

- EEG patterns may suggest brain injury, e.g. burst suppression
- Somato-sensory evoked potentials – bilateral absence of the N20 spike (recorded from scalp electrodes from cutaneous electrical impulse over the median nerve)

---

**Critical care medicine**

### Decisions around intensive care admission

Being a patient in intensive care is seldom a pleasant experience. The interventions are usually painful and the loss of liberties that are normally taken for granted can be devastating. While much of the unpleasant sensory and emotional experience can be modified with high-quality care and analgesia, there is a strong case that it can only be morally ‘right’ to admit a patient to intensive care if the end justifies the means. There must be a realistic hope that the patient will regain a quality of life that would be worth the pain and suffering that he or she will experience in intensive care. Few patients are able to comprehend fully what it means to be critically ill, so the physician should guide the process of determining who should be admitted to intensive care.

Selecting the appropriate level of intervention for an individual patient can be very difficult. The decision-making process should involve an assessment of the likelihood of reversibility of the disease, the magnitude of the interventions required, the underlying level of frailty, and the personal beliefs and wishes of the patient (commonly expressed through their next of kin).

As technology and science have improved, conditions that were previously regarded as terminal can now be supported and life can be considerably prolonged (Box 10.37). There have been several prominent examples of individuals who have received intensive care, but where an onlooker might have considered treatment to be futile owing to frailty, comorbidity or profound neurological injury. Such cases will, in part, shape the views and expectations of society, and it is unlikely that making decisions in this area will become any easier. Some suggested techniques to aid decision-making are listed in Box 10.38.
Non-invasive respiratory support provides a bridge between simple oxygen delivery devices and invasive ventilation. It can be used in patients who are in respiratory distress but do not have an indication for invasive ventilation, or in those who are not suitable for intubation and ventilation for chronic health reasons. Patients must be cooperative, able to protect their airway, and have the strength to breathe spontaneously and cough effectively. Clinicians should avoid using non-invasive respiratory support to prolong the dying process in irreversible conditions such as end-stage lung disease. Likewise, a failure to respond to treatment or further deterioration should trigger a decision regarding intubation, as delayed invasive ventilation in this context is associated with worse outcome.

High-flow nasal cannulae

High-flow nasal cannulae (HFNCs) are devices that provide very high gas flows of fully humidified oxygen and air. They offer distinct advantages over non-invasive ventilation (NIV) in selected patients, mainly those with type I respiratory failure (particularly pneumonia) who have not reached an indication for invasive ventilation. They allow patient comfort and increased expectoration while providing some degree of positive end-expiratory pressure (PEEP) and a high oxygen concentration that can be titrated to the SO2.

Continuous positive pressure ventilation

Continuous positive pressure ventilation therapy involves the application of a continuous positive airway pressure (CPAP) throughout the patient’s breathing cycle, typically 5–10 cmH2O. It helps to recruit collapsed alveoli and can enhance clearance of alveolar fluid. It is particularly effective at treating pulmonary atelectasis (which may be post-operative) and pulmonary oedema. It uses a simpler device than NIV but otherwise offers no direct benefit over it.

Non-invasive ventilation or bi-level ventilation

NIV provides ventilatory support via a tight-fitting nasal or facial mask. It can be delivered by using a simple bi-level ventilation (BiPAP) turbine ventilator, or an intensive care ventilator. These machines can deliver pressure at a higher level (approximately 15–25 cmH2O) for inspiration and a lower pressure (usually 4–10 cmH2O) to allow expiration. Ventilation can be spontaneous (triggered by a patient’s breaths) or timed (occurring at a set frequency). Systems that synchronise with a patient’s efforts are better tolerated and tend to be more effective in respiratory failure. Timed breaths are used for patients with central apnoea. NIV is the first-line therapy in patients with type II respiratory failure secondary to an acute exacerbation of COPD because it reduces the work of breathing and offloads the diaphragm, allowing it to recover strength. It is also useful in pulmonary oedema, obesity hypoventilation syndromes and some neuromuscular disorders. It should be initiated early, especially when severe respiratory acidosis secondary to hypercapnia is present. NIV can also be used to support selected patients with hypercapnia secondary to pneumonia, or during weaning from invasive ventilation, but its effectiveness in these contexts is less certain; early intubation or re-intubation is probably more beneficial.
**Intubation and intermittent positive pressure ventilation**

Taking control of the respiratory system in a critically ill patient is one of the most significant and risky periods in a patient’s journey. Critical incidents are common because the patient is often deteriorating rapidly and is exhausted. The potential for cardiovascular collapse is further exacerbated by the negatively inotropic and vasodilating drugs used to induce anaesthesia, and the period of apnoea invoked to facilitate intubation (Box 10.39).

The main aims of intermittent positive pressure ventilation (IPPV) are to avoid critical hypoxaemia and hypercapnia while minimising damage to the alveoli and encouraging the patient to breathe spontaneously once it is safe to do so. The determination of what constitutes critical will depend on the status of each patient. For example, a patient with raised ICP will have a strong indication for normocapnia (because hypercapnia increases ICP). Unfortunately, achieving the minute volumes required to maintain normocapnia can, in itself, be harmful to the lungs (p. 204).

**Ventilator modes**

Following intubation, most patients have a period of paralysis from the muscle relaxation. Mandatory ventilation is, therefore, required for a variable period, depending on the severity of the lung injury, the underlying disease process and the general condition of the patient. Mandatory ventilation means that the ventilator will deliver set parameters (either a set tidal volume or a set inspiratory pressure), regardless of patient effort. A physician can choose to support additional patient effort in between mandatory breaths with pressure support. This requires sufficient patient effort to ‘trigger’ the ventilator to deliver a synchronised breath, in time with the patient’s own ventilation. Other parameters that should be considered when using mechanical ventilation are shown in Figure 10.18.

As a patient’s illness resolves, or if the lung injury necessitating intubation is not severe, periods of spontaneous breathing with pressure support are commenced. While spontaneous breathing is preferable to mandatory ventilation modes, the shearing forces of patient effort can exacerbate lung injury in patients with severely damaged lungs. It is, therefore, important that a patient is permitted to breathe in a planned and controlled way.

**10.39 Optimising safety during intubation**

- Intervene early in the disease process (once it has become clear that the disease trajectory is downward)
- Use a stable anaesthetic technique: low doses of sedative agents and rapidly acting paralytic agents
- Remember that intubation should be performed by the most experienced operator available
- Use techniques to optimise oxygenation and ventilation in the period around intubation, e.g. keeping non-invasive ventilation in situ for pre-oxygenation, leaving high-flow nasal cannulae on for the intubation process, and using a video-laryngoscope in an anticipated difficult intubation

**Plateau pressure**

The pressure within the respiratory system during expiration, commonly 5–15 cmH₂O. Higher levels of PEEP often improve oxygenation but put strain on the right heart (as it makes it harder to pump blood through the pulmonary circulation)

**Respiratory rate and minute volume**

Depend on the minute volume required to achieve the desired PCO₂, and whether the patient is breathing spontaneously. Rates are commonly 20–30 breaths/min

**Ventilator mode**

Mandatory, spontaneous, or mandatory with the ability to take spontaneous breaths (as shown here)

**Fraction of inspired oxygen (FiO₂)**

This is usually titrated to oxygen saturations targeting 92–95%

**Tidal volume**

Usual target is 6 mL/kg of predicted body weight (PBW)

**Fig. 10.18** Settings to be considered when commencing mechanical ventilation.
**Ventilator-induced lung injury**

Every positive-pressure breath causes cyclical inflation of alveoli followed by deflation. The resultant damage to alveoli occurs via several possible mechanisms:
- Distending forces from the tidal volume, termed ‘volutrauma’
- The pressure used to inflate the lung, referred to as ‘barotrauma’
- Alveoli collapsing at the end of expiration, called ‘atelectotrauma’
- The release of inflammatory cytokines in response to the lung, called ‘biotrauma’.

The threshold of injurious ventilation is unique to each patient. Moderate ventilator pressures and volumes used to ventilate healthy lungs may not cause ventilator-induced lung injury (VILI), but the same settings may cause significant VILI if delivered to a patient with lungs that are already damaged from another disease process.

Strategies that may reduce the incidence and severity of VILI include:
- **Permissive hypercapnia.** In the majority of patients who are ventilated for respiratory failure, it is preferable to tolerate moderate degrees of hypercapnia rather than strive for normal blood gases at the expense of VILI. For example, in a patient with isolated respiratory failure, a physician may choose to tolerate a PaCO₂ of up to 10 kPa (75 mmHg), provided the H⁺ is < 63 nmol/L (pH > 7.2).
- **‘Open lung’ ventilation.** Maintaining a positive pressure within the airways at the end of expiration prevents atelectotrauma. Use of low tidal volumes, higher levels of PEEP (Fig. 10.18) and recruitment manoeuvres (occasional short periods of sustained high airway pressures to open up alveoli that have collapsed) can reduce the incidence of VILI.
- **Paralysis.** When respiratory failure is severe, patient effort may worsen VILI. An infusion of muscle relaxant can be used to moderate dyssynchrony with the ventilator.

**Advanced respiratory support**

**Airway pressure release ventilation**

Airway pressure release ventilation (APRV) is a mode of ventilation that lengthens the inspiratory time to the extreme, with a very short period of time for expiration. It relies on spontaneous movement of the diaphragm from patient effort to facilitate the mixing of gas within the respiratory system during the long period in full inspiration, followed by a very short period of low pressure to allow passive expiration. It has not, however, been demonstrated to be superior to conventional modes of ventilation, but may have a role in moderate to severe ARDS.

**Prone positioning**

In ARDS, the posterior parts of the lung lose airspaces due to atelectasis and inflammatory exudate. By placing patients on their front, the pattern of fluid distribution within the lung changes, and ventilation–perfusion matching is improved. This is used to enhance oxygenation in moderate to severe ARDS, and may have some disease-modifying effects as the dependent areas of the lung are changed periodically. Although there are risks associated with nursing a patient in the prone position, it is becoming a widespread therapy. Patients are usually placed in the prone position for 12–24 hours and then rotated back to the supine position for a similar period. This cycle continues until there is evidence of resolving lung injury.

**Extracorporeal respiratory support**

Sometimes, despite optimal invasive ventilation, it is not possible to maintain adequate oxygenation or prevent a profound respiratory acidosis. When a patient has a reversible cause of respiratory failure (or is a potential lung transplant recipient) and facilities are available, extracorporeal respiratory support should be considered.

**Venous–venous extracorporeal membrane oxygenation**

In venous–venous extracorporeal membrane oxygenation (VV ECMO), large-bore central venous cannulae are inserted into the superior vena cava (SVC) and/or the inferior vena cava (IVC) via the femoral or jugular veins, and advanced under ultrasound or fluoroscopic guidance (Fig. 10.19). Venous blood is then pumped through a membrane oxygenator. This device has thousands of tiny silicone tubes with air/oxygen gas on the other side of the tubes (the membrane). This facilitates the passage of oxygen into the blood and diffusion of carbon dioxide across the membrane, where it is removed by a constant flow of gas (sweep gas). The oxygenated blood is then returned to the right atrium, from where it flows through the lungs as it would in the physiological state. This means that even if the lungs are contributing no oxygenation or carbon dioxide removal, a patient can remain well oxygenated and normocapnic.

**Extracorporeal carbon dioxide removal**

In some patients it is possible to maintain oxygenation but there is refractory hypercapnia. There are devices available that can remove carbon dioxide using a much lower blood flow rate than VV ECMO. Consequently, smaller venous cannulae, similar to those used in renal dialysis, can be sufficient to have a ‘CO₂ dialysis’ effect. This can be useful in patients in whom normocapnia is essential (such as those with a raised ICP), or those with refractory hypercapnia and adequate oxygenation. In addition, extracorporeal carbon dioxide removal can be used to reduce the required minute volume, which is a beneficial strategy for protecting the lungs against VILI or facilitating early extubation.

**Cardiovascular support**

**Initial resuscitation**

A brief assessment can usually yield enough information to determine whether a patient is at significant risk of an imminent cardiac arrest. If the patient is obtunded and there is no palpable radial or brachial pulse, then treatment should proceed as described on page 457.

In anaphylactic shock, or undifferentiated shock in a peri-arrest situation, a single dose of intramuscular adrenaline (epinephrine) 0.5 mg (0.5 mL of 1 : 1000) can be life-saving. If expertise is available, a small dose of intravenous adrenaline can delay cardiac arrest long enough to identify the cause of shock and institute other supportive measures; a suggested dose would be 50 μg (0.5 mL of 1 : 10 000). If haemorrhage is considered a possibility, a ‘major haemorrhage’ alert should be activated, facilitating rapid access to large volumes of blood and blood products. A classification of shock is shown in Box 10.40.
**Fig. 10.19 Principles of extracorporeal membrane oxygenation (ECMO).**

A Basic ECMO circuit: venous–arterial (VA) and venous–venous (VV).

B Example of a VV ECMO circuit.

C Example of a VA ECMO circuit.
Venous access for the administration of drugs and fluids is vital but often difficult in critically unwell patients. Wide-bore cannulae are required for rapid fluid administration. In extremis, the external jugular vein can be cannulated; it is often prominent and readily visible on the lateral aspect of the neck. Occluding the vein distally with finger pressure makes it easier to cannulate, but care must be taken to remain high in the neck to avoid causing a pneumothorax. Intra-osseous access makes it easier to cannulate, but care must be taken to remain high in the neck to avoid causing a pneumothorax. Ultrasound can provide assistance for cannulating the external jugular vein can be cannulated; it is often prominent and readily visible on the lateral aspect of the neck. Occluding the vein distally with finger pressure makes it easier to cannulate, but care must be taken to remain high in the neck to avoid causing a pneumothorax.

### Fluid and vasopressor use

Resuscitation of the shocked patient should include a 10 mL/kg fluid challenge. Using colloid or crystalloid is acceptable; starch solutions are associated with additional renal dysfunction and should be avoided. The fluid challenge can be repeated if shock persists, to a maximum total of 30 mL/kg of fluid. However, commencing vasopressor therapy early in resuscitation is better than delaying until a large volume of fluid has been given. Amongst other beneficial effects, vasopressors induce venoconstriction, reducing the capacitance of the circulation and effectively mobilising more fluid into the circulation.

If a patient remains shocked after 30 mL/kg of fluid has been administered, a re-evaluation of the likely cause is required, looking particularly for concealed haemorrhage or an obstructive pathology. A bedside echocardiogram is especially useful at this stage to evaluate cardiac output and exclude tamponade. Noradrenaline (norepinephrine) should be commenced as the first-line vasoactive agent in most cases, unless there is a strong indication to use a pure inotropic or chronotropic agent; for example, in cardiogenic shock or shock associated with bradycardia. If there is evidence of low cardiac output, adrenaline (epinephrine) or dobutamine should be commenced. Both agents are equally effective, but dobutamine causes more vasodilatation and additional noradrenaline may be required to maintain an adequate MAP. Vasopressin is added if hypertension persists despite high doses of noradrenaline and cardiac output is thought to be adequate.

In extreme situations it is acceptable to start infusions of inotropic drugs through a well-sited, large-bore peripheral cannula, although central venous access and an arterial line (for monitoring) should be inserted as soon as possible. The actions of commonly used vasoactive drugs are summarised in Box 10.41.

### Advanced haemodynamic monitoring

There are many different devices available to estimate cardiac output. Such devices employ a variety of mechanisms, including the Doppler effect of moving blood, changes in electrical impedance of the thorax, or the dilution of either an indicator substance or heat (thermodilution). The information is processed within the equipment, and often integrated with additional data, such as the arterial pressure waveform, to give an estimate of cardiac output and stroke volume.

When the aetiology of shock is straightforward and the patient is responding as predicted to treatment, the value of devices that estimate cardiac output is limited. Portable echocardiography has the advantage of giving qualitative information – for example, demonstrating aortic stenosis or a regional wall motion abnormality – as well as quantitative information on stroke volume, but it requires technical expertise.

Pulmonary artery (PA) catheters, sometimes referred to as Swan–Ganz catheters (Fig. 10.20), are invasive but provide useful information on pulmonary pressures, cardiac output, mixed venous oxygen saturations (see Box 10.30) and, by extrapolation, whether the cause of the shock is vasodilatation or pump failure. They can be helpful in complex cases, such as shock after cardiac surgery, or in patients with suspected pulmonary hypertension (Box 10.42). However, PA catheters are associated with some rare but serious complications, including lung infarction, PA rupture and thrombosis of the catheter itself. Such complications occur infrequently in centres that use PA catheters regularly; it should be stressed that a lack of familiarity within the wider clinical team is a relative contraindication to their use.

### Mechanical cardiovascular support

When shock is so severe that it is not possible to maintain sufficient organ perfusion with fluids and inotropic support, it is...
Stabilisation and institution of organ support

in cardiogenic shock. There are risks associated with thrombosis formation on the balloon, mesenteric ischaemia and femoral artery pseudo-aneurysm following removal of the device.

Venous–arterial extracorporeal membrane oxygenation

Venous–arterial extracorporeal membrane oxygenation (VA ECMO) can be life-saving in profound cardiogenic shock and has even been used effectively in refractory cardiac arrest. The circuit and principles are very similar to those described in ‘VV ECMO’ above (see p. 204 and Fig. 10.19) with one important difference: oxygenated blood is returned to the arterial system (rather than into the right atrium). This means that the pump needs to generate sufficient pressure to allow blood to flow

sometimes necessary to use an internal device to augment or replace the inadequate native cardiac output.

Intra-aortic balloon pump

An intra-aortic balloon counter-pulsation device is a long tube that is usually inserted into the femoral artery and fed proximally into the thoracic aorta. The basic principle is that a helium-filled balloon is able to inflate and deflate rapidly in time with the cardiac cycle. It is inflated in diastole, thus augmenting forward flow of blood to the abdominal organs and improving diastolic pressure proximal to the balloon, thereby optimising coronary perfusion. While the principle is appealing, and an intra-aortic balloon pump (IABP) is often effective in achieving predetermined physiological goals, this does not translate into improved survival

Fig. 10.20 A pulmonary artery (Swan–Ganz) catheter. A. There is a small balloon at the tip of the catheter and pressure can be measured through the central lumen. The catheter is inserted via an internal jugular, subclavian or femoral vein and advanced through the right heart until the tip lies in the pulmonary artery. When the balloon is deflated, the pulmonary artery pressure can be recorded. B. Advancing the catheter with the balloon inflated will ‘wedge’ the catheter in the pulmonary artery. Blood cannot then flow past the balloon, so the tip of the catheter will now record the pressure transmitted from the pulmonary veins and left atrium (known as the pulmonary artery capillary wedge pressure), which provides an indirect measure of the left atrial pressure. (LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle)

through the systemic circulation. The sites of venous and arterial access can be either central (via a thoracotomy or sternotomy) or peripheral via cannulae in the IVC/SVC and the femoral/subclavian artery. If the return cannula is peripherally sited (e.g. in the femoral artery), blood will flow back up the aorta from distal to proximal and perfuse the organs.

The outcome depends on the avoidance of complications (primarily, bleeding at the cannula site, intracranial haematoma, air embolism, infection and thrombosis) and improvement of the underlying condition. Most causes of profound cardiogenic shock are unlikely to resolve, and the potential availability of a longer-term solution, such as cardiac transplantation or insertion of a ventricular assist device, is a prerequisite for commencing VA ECMO in most centres.

Renal support

Renal replacement therapy (RRT) is explained in detail on page 420. The key points relating to RRT in an intensive care context are:

- Haemodynamic instability is common. Continuous therapies are widely believed to cause less haemodynamic instability than intermittent dialysis. However, many units use intermittent dialysis without significant problems.
- Haemodialysis and haemofiltration are equally good. Although there are theoretical benefits to removing inflammatory cytokines with haemofiltration, this does not translate into improved survival.
- Anticoagulation is usually achieved using citrate or heparin. Citrate has a better profile for anticoagulating the extracorporeal circuit without inducing an increased bleeding risk, but may accumulate in patients with profound multi-organ failure and should be avoided in very unstable individuals.
- Most patients who survive intensive care will regain adequate renal function to live without long-term renal support.
- A thorough investigation for reversible causes of renal dysfunction should always be undertaken in conjunction with instigation of renal support (see Fig. 15.18, p. 411).
- Shock appears to reverse more rapidly when renal support is instituted. Commencing renal support soon after a patient develops renal ‘injury’ (when serum creatinine is more than two times higher than baseline) is probably beneficial in the context of septic shock.

Neurological support

A diverse range of neurological conditions require management in intensive care. These include the various causes of coma, spinal cord injury, peripheral neuromuscular disease and prolonged seizures.

The goals of care in such cases are to:

- Protect the airway, if necessary by endotracheal intubation.
- Provide respiratory support to correct hypoxaemia and hypercapnia.
- Treat circulatory problems, e.g. neurogenic pulmonary oedema in subarachnoid haemorrhage, autonomic disturbances in Guillain–Barré syndrome, and spinal shock following high spinal cord injuries.
- Manage acute brain injury with control of ICP.

- Manage status epilepticus using antiepileptic agents such as levetiracetam, phenytoin and benzodiazepines. In refractory cases an infusion of sodium thiopental or ketamine may be required.

   The aim of management in acute brain injury is to optimise cerebral oxygen delivery by maintaining normal arterial oxygen content and a cerebral perfusion pressure (CPP) of >60 mmHg. Secondary insults to the brain, such as hypoxaemia, hyper-/hypoglycaemia and prolonged seizures, must be avoided. ICP rises in acute brain injury as a result of haematoma, contusions, oedema or ischaemic swelling. Raised ICP causes damage to the brain in two ways: direct damage to the brainstem and motor tracts as a result of downward pressure and herniation through the tentorium cerebelli and foramen magnum, and indirect damage by reducing CPP. Cerebral blood flow is dependent on an adequate CPP. The CPP is determined by the formula:

   \[
   \text{CPP} = \text{MAP} - \text{ICP}
   \]

   ICP can be measured by pressure transducers that are inserted directly into the brain tissue. The normal upper limit for ICP is 15 mmHg and an upper acceptable limit of 20 mmHg is usually adopted in intensive care. Sustained pressures of >30 mmHg are associated with a poor prognosis. Various strategies are used to control ICP; maintaining normocapnia, preventing any impedence to venous drainage from the head, giving osmotic agents such as mannitol and hypertonic saline, and using hypothermia and decompressive cranectomy. No single technique has been shown to improve outcome in severe intracranial hypertension.

   CPP should be maintained above 60 mmHg by ensuring adequate fluid replacement and, if necessary, by treating hypotension with a vasopressor such as noradrenaline (norepinephrine). Complex neurological monitoring must be combined with frequent clinical assessment of GCS, pupillary response to light, and focal neurological signs.

Daily clinical management in intensive care

Clinical review

In intensive care, detailed clinical examination should be performed daily to identify changes to a patient’s condition and review the latest diagnostic information. Further focused clinical reviews are usually incorporated into twice-daily ward rounds. Each ward round offers an ideal opportunity to monitor and document compliance with relevant care bundles. A care bundle is a group of interventions that, when implemented concurrently, have provided evidence of clinical benefit. The mnemonic ‘FAST HUG’ provides a useful checklist of interventions that reduce intensive care complications: feeding, analgesia, sedation, thromboprophylaxis, head of bed elevation (to reduce the incidence of passive aspiration), ulcer prophylaxis and glucose control.

Other key aspects of the daily review are outlined on page 174. The overarching aim of the review is to identify the issues that are impeding recovery from critical illness, and make alterations to address them. In addition, specific and realistic goals for each relevant organ system should be defined, facilitating the autonomous titration of therapy by the bedside critical care nurse. An example of daily goals may be: ‘Titrate the noradrenaline (norepinephrine) to achieve a MAP of 65 mmHg, aim for a negative fluid balance, titrate \( FO_2 \) to achieve oxygen saturations...’
Delirium is discussed on page 183. It is extremely common in critically ill patients and often becomes apparent as sedation is reduced. Hypoactive delirium is far more common than hyperactive delirium, but is easily missed unless routine screening is undertaken. A widely used bedside assessment is the CAM-ICU score. The patient is requested to squeeze the examiner’s hand in response to instruction and questions, aiming to ascertain whether disordered thought or sensory inattention is present.

Delirium of any type is associated with poorer outcome. Management is focused on non-pharmacological interventions such as early mobilisation, reinstatement of day–night routine, noise reduction, cessation of drugs known to precipitate delirium, and treatment of potential underlying causes such as thiamin replacement in patients at risk of Wernicke’s encephalopathy. Patients with agitation delirium that is refractory to verbal de-escalation should initially be managed with small doses of intramuscular antipsychotics, changed to the enteral route once control is established. Atypical antipsychotics such as olanzapine and quetiapine are more efficacious than traditional drugs such as haloperidol. Pharmacological interventions are not useful as prophylaxis or in hypoactive delirium. Additional information on diagnosis and management of delirium can be found on page 184.

Weaning from respiratory support

As the condition that necessitated ventilation resolves, respiratory support is gradually reduced: the process of ‘weaning’ from ventilation. Some approaches to weaning are described below.
Spontaneous breathing trials

A spontaneous breathing trial involves the removal of all respiratory support followed by close observation of how long the patient is able to breathe unassisted. The technique is particularly effective when linked to a reduction in sedation. PEEP and pressure support are reduced to low levels, or patients are disconnected from the ventilator and breathe oxygen or humidified air through the endotracheal tube. Signs of failure include rapid shallow breathing, hypoxaemia, rising $\text{PaCO}_2$, sweating and agitation. Patients who pass a spontaneous breathing trial are assessed for suitability of extubation (endotracheal tube removal).

Progressive reduction in pressure support ventilation

Progressive reduction in pressure support ventilation (PSV) is applied to each breath over a period of hours or days, according to patient response. Some ICU ventilators have software that allows the facility to wean the support provided automatically.

A useful tool to guide the weaning process is the rapid shallow breathing index (RSBI). This composite score of a patient’s spontaneous respiratory rate and tidal volume (respiratory rate divided by tidal volume in litres) gives a numerical indication of how difficult the patient is finding breathing at that particular level of support. A RSBI value of $>100$ suggests that a patient is working at a level that would be unsustainable for longer periods.

Extubation

It is not possible to predict whether a patient is ready to be extubated accurately; the timing relies heavily on clinical judgement. There are, however, some simple rules that can aid decision-making. Patients must have stable ABGs with resolution of hypoxaemia and hypercapnia despite minimal ventilator pressure support and a low $\text{FiO}_2$. Conscious level must be adequate to protect the airway, comply with physiotherapy, and cough. Furthermore, an assessment must be made as to whether the patient can sustain the required minute volume without ventilator support. This depends on the condition of patients’ lungs, their strength and other factors affecting the $\text{PaCO}_2$, such as temperature and metabolic rate. The need for re-intubation following extubation is associated with poorer outcome, but patients who are not given the opportunity to breathe without a ventilator will also be at increased risk of ventilator-associated complications such as pneumonia and myopathy.

Tracheostomy

A tracheostomy is a percutaneous tube passed into the trachea (usually between the first and second, or second and third tracheal rings) to facilitate longer-term ventilation. The advantages and disadvantages of tracheostomy insertion are listed in Box 10.45.

When ventilation weaning has been unsuccessful, a tracheostomy provides a bridge between intubation and extubation; the patient can have increasing periods free of ventilator support but easily have support reinstated. A tracheostomy can be inserted percutaneously, using a bronchoscope in the trachea for guidance, or surgically under direct vision. Occasionally, a patient will have a tracheostomy in situ following a laryngectomy. Such patients are important to identify, as emergency management in the event of a tracheostomy problem (blockage or displacement) must be through the tracheostomy site; access will not be possible via the upper airway.

Nutrition

It is crucial that critically ill patients receive adequate calories, protein and essential vitamins and minerals. Calculation of exact requirements is complex and requires the expertise of a diettian. It is, however, useful to make a rough estimation of requirements (p. 705). Under-feeding leads to muscle wasting and delayed recovery, while over-feeding can lead to biliary stasis, jaundice and steatosis. Enteral feeding is preferred where possible because it avoids the infective complications of total parenteral nutrition (TPN) and helps to maintain gut integrity. However, TPN is recommended for patients who are likely to have a sustained period without effective enteral feeding, or who are already malnourished. Caution must be taken to avoid the consequences of refeeding syndrome (p. 706).

Other essential components of intensive care

Survival after critical illness depends, to a large extent, on the prevention of medical complications during recovery from the primary insult.

Thromboprophylaxis

DVT, venous catheter-related thrombosis and PE are common in critically ill patients. Low-molecular-weight heparin (LMWH) should be administered to all patients, unless there is a contraindication. Often patients at highest risk of thrombosis, such as those with hepatic dysfunction or those who have suffered major trauma, have a relative contraindication to heparin. Such cases mandate daily evaluation of the risk–benefit ratio, and LMWH should be administered as soon as it is deemed safe to do so. Mechanical thromboprophylaxis, such as intermittent calf compression devices, are useful adjuvants in high-risk patients.

Glucose control

Hyperglycaemia is harmful in critical illness and may occur in people with pre-existing diabetes or undiagnosed diabetes, following administration of high-dose glucocorticoids, or as

| **Disadvantages**                                 |
| • Immediate complications: hypoxaemia, haemorrhage |
| • Tracheostomy site infection                     |
| • Tracheal damage; late stenosis                  |
a consequence of ‘stress hyperglycaemia’. Hyperglycaemia is commonly managed by infusion of intravenous insulin titrated against a ‘sliding scale’. Intensive management of hyperglycaemia with insulin can result in hypoglycaemia, which may also be harmful in critical illness. Therefore, a compromise is to titrate insulin to a blood glucose level of 6–10 mmol/L (108–180 mg/dL).

**Blood transfusion**

Many critically ill patients become anaemic due to reduced red cell production and red cell loss through bleeding and blood sampling. However, red cell transfusion carries inherent risks of immunosuppression, fluid overload, organ dysfunction from microemboli, and transfusion reactions. In stable patients, a haemoglobin level of 70 g/L (7 g/dL) is a safe compromise between optimisation of oxygen delivery and the risks of transfusion. This transfusion threshold should be adjusted upwards for situations where oxygen delivery is critical, such as in patients with active myocardial ischaemia.

**Peptic ulcer prophylaxis**

Stress ulceration during critical illness is a serious complication. Proton pump inhibitors or histamine-2 receptor antagonists are effective at reducing the incidence of ulceration. There is, however, a suggestion that the use of these agents, particularly in conjunction with antibiotics, may increase the incidence of nosocomial infection, especially with *Clostridium difficile* (p. 264). It is therefore common practice to stop ulcer prophylaxis once consistent absorption of enteral feed is established.

---

**Complications and outcomes of critical illness**

The majority of patients will survive their episode of critical illness. While some will return to full, active lives, there are many who have ongoing physical, emotional and psychological problems.

**Adverse neurological outcomes**

**Brain injury**

Head injury, hypoxic–ischaemic injury and infective, inflammatory and vascular pathologies can all irreversibly injure the brain. If treatment is unsuccessful, patients will either die or be left with a degree of disability. In the latter situation, the provision of ongoing organ support will depend on the severity of the injury, the prognosis, and the wishes of the patient (usually expressed via relatives). Brain death is a state in which cortical and brainstem function is irreversibly lost. Diagnostic criteria for brain death vary between countries (Box 10.46); if satisfied, these criteria allow physicians to withdraw active treatment and discuss the potential for organ donation. Diagnosing brain death is complex and should be done only by physicians with appropriate expertise, as clinical differentiation from reduced consciousness can be challenging (Box 10.47). Where there is doubt – for example, in patients with coexisting spinal injury or localised brainstem pathology – additional investigations should be performed.

The ‘locked-in’ syndrome, in which the patient is paralysed except for eye movements, requires preserved hemispheric function (and thus consciousness), but a lesion in the ventral pons (usually caused by infarction) results in complete paralysis. The term ‘vegetative state’ implies some retention of brainstem function and minimal cortical function, with loss of awareness of the environment. In contrast, ‘minimally conscious state’ implies that there is some degree of awareness and intact brainstem function. Confident distinction between these states is important and requires careful assessment, often over a period of time. Brain death is, by definition, irreversible but other states may offer hope for improvement.

**ICU-acquired weakness**

Weakness is common among survivors of critical illness. It is usually symmetrical, proximal and most marked in the lower limbs. Critical Illness polyneuropathy and myopathy can occur simultaneously and, within the constraints of an altered sensorium, it can be impossible to distinguish the two conditions clinically. Risk factors for both processes include the severity of multi-organ failure, poor glycaemic control and the use of muscle relaxants and glucocorticoids.

**Critical illness polyneuropathy**

This is due to peripheral nerve axonal loss and characteristically presents as proximal muscle weakness with preserved sensation.
Critical illness myopathy

Although loss of muscle bulk is related to immobility and the catabolic state of critical illness, it is likely that microvascular and intracellular pathophysiological processes are also involved in critical illness myopathy. These processes result in loss of actin myofibrils and muscle weakness. Typically, the CK is normal or only mildly elevated. Like critical illness polyneuropathy, critical illness myopathy is usually a clinical diagnosis. Nerve conduction studies and electromyography may be suggestive of critical illness myopathy, and helpful in ruling out other pathology, but a muscle biopsy is required to confirm the diagnosis (p. 1076). It characteristically shows selective loss of the thick myofibrils and muscle necrosis. Management is conservative and the prognosis is good in ICU survivors.

Other long-term problems

The experience of critical illness and the necessary invasive management can leave patients with profound psychological sequelae akin to the post-traumatic stress syndrome seen in many survivors of conflict. Specialist help is required in managing these issues. Sometimes recovering patients benefit from returning to the ICU to see the environment in a different way and gain a better understanding of the processes and procedures that haunt them.

Long-term physical consequences are also common. Many diseases are not completely cured but follow a relapsing–remitting course; patients who have been critically ill with sepsis are far more likely than others in the general population to suffer from it again. Organ damage often persists and iatrogenic complications are common (e.g. damage to the vocal cords or tracheal stenosis from mucosal pressure caused by the cuff of the endotracheal tube). Intensive care follow-up clinics provide an excellent forum for addressing such issues, and for coordinating care involving a variety of medical specialties.

The older patient

Critically ill older patients present additional challenges following intensive care discharge (Box 10.48). As the ability to make a full recovery depends on frailty rather than chronological age, it can be helpful to use a validated frailty scoring system (p. 1306) to inform admission decision-making.

Rehabilitation medicine has much to offer survivors of critical illness, and an early referral is beneficial when it is clear that a patient is likely to survive with significant morbidity.
The diagnosis of brain death is discussed on page 211. Once brain death has been confirmed, consideration should be given to organ donation, termed ‘donation after brain death’ (DBD). Time of death is recorded as the time when the first series of brain death tests are undertaken, although the deceased patient continues to be ventilated. The practice of organ donation varies throughout the world but the principles remain the same.

Organ donation specialists are contacted and they begin the process of establishing the suitability of any organs for transplantation and matching potential recipients. Many patients will have expressed their wishes through an organ donor registration scheme but agreement of family and next of kin is a moral (and sometimes legal) prerequisite. Once the organ retrieval theatre team have been assembled and all preliminary tests have been completed, the deceased patient is transferred to the operating theatre and the organs are sequentially removed.

**Donation after cardiac death**

If a patient does not meet brain death criteria but withdrawal of treatment has been agreed, donation of organs with residual function may be appropriate. This is termed ‘donation after cardiac death’ (DCD). If the patient dies within a short period following the commencement of ‘warm ischaemic time’ (the time to asystole following the onset of physiological derangement after the withdrawal of active treatment), then DCD can proceed. The deceased patient is transferred to an operating theatre and the agreed organs (often lungs, liver, kidney and pancreas) are retrieved. As heart valves and corneas can be retrieved later (within a longer time frame), tissue retrieval may occur in the mortuary.

**Withdrawal of active treatment and death in intensive care**

**Futility**

The idea of futility is not new: Hippocrates stated that physicians should ‘refuse to treat those who are overmastered by their disease, realising that in such cases medicine is powerless’. In intensive care, where the concept of futility is often used as a criterion to limit or withdraw life-sustaining treatment, it is helpful to have a working definition on which families and physicians can agree. It is, therefore, reasonable to define futility in such circumstances as the point at which recovery to a quality of life that the patient would find acceptable has passed. The primary insult may be neurological (irreversible brain injury not meeting criteria for brain death), or multi-organ failure that is refractory to treatment.

**Death**

Whilst most patients prefer to die at home, many spend their final days in hospital. Chapter 34 details the medical, legal and ethical priorities that should guide patient management once the decision to withdraw active treatment has been made (p. 1354). The decision to shift the focus of care to palliation should not change its intensity; it is the over-arching objective that changes. Only interventions that will improve the quality of a patient’s remaining life should be offered. In the ICU, it is often appropriate to continue infusions of sedatives and analgesics, as reducing or stopping them may cause unnecessary pain and agitation. Measures that were instituted to prolong life should be withdrawn (usually including cessation of inotropes and extubation) to allow the patient to die peacefully with their family and friends present.

**Organ donation**

**Donation after brain death**

Admission and discharge criteria vary between ICUs, so it is important to define the characteristics of the patients admitted in
order to assess the effects of the care provided on the outcomes achieved. Two systems are widely used to measure severity of illness (see Box 10.50 for further details):

- **APACHE II**: Acute Physiology Assessment and Chronic Health Evaluation
- **SOFA score**: Sequential Organ Failure Assessment tool.

When combined with the admission diagnosis, scoring systems have been shown to correlate well with the risk of death in hospital. Such outcome predictions are useful at a population level but lack the specificity to be of use in decision-making for individual patients. This is in contrast to well-validated, disease-specific tools, such as the CURB-65 tool for pneumonia, which can be helpful in guiding individual management (see Fig. 17.32, p. 583).

Predicted mortality figures by diagnosis have been calculated from large databases generated from a range of ICUs. These allow a particular unit to evaluate its performance compared to the reference ICUs by calculating standardised mortality ratios (SMRs) for each diagnostic group. A value of unity indicates the same performance as the reference ICUs, while a value below 1 indicates a better than predicted outcome. If a unit has a high SMR in a certain diagnostic category, it should prompt investigation into the management of patients with that diagnosis, in order to identify aspects of care that could be improved.

- Erythema nodosum (D and Box 29.33, p. 1265)

*Always consider non-infectious aetiologies in the differential diagnosis. (HBV/HCV = hepatitis B/C virus; HIV-1 = human immunodeficiency virus-1; TB = tuberculosis)*
The principles of infection and its investigation and therapy are described in Chapter 6. This chapter and the following ones on human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) and sexually transmitted infection (STI) describe the approach to patients with potential infectious disease, the individual infections and the resulting syndromes.

### Presenting problems in infectious diseases

Infectious diseases present with myriad clinical manifestations. Many of these are described in other chapters or below.

#### Fever

‘Fever’ implies an elevated core body temperature of more than 38.0°C (p. 138). Fever is a response to cytokines and acute phase proteins (pp. 65 and 70), and occurs in infections and in non-infectious conditions.

**Clinical assessment**

The differential diagnosis is very broad so clinical features are used to guide the most appropriate investigations. The systematic approach described on page 216 should be followed. Box 11.1 describes the assessment of elderly patients.

**Investigations**

If the clinical features do not suggest a specific infection, then initial investigations should include:

- a full blood count (FBC) with differential, including eosinophil count
- urea and electrolytes, liver function tests (LFTs), blood glucose and muscle enzymes
- inflammatory markers, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- a test for antibodies to HIV-1 (p. 310)
- autoantibodies, including antinuclear antibodies (ANA)
- chest X-ray and electrocardiogram (ECG)
- urinalysis and urine culture
- blood culture (p. 106)
- throat swab for culture or polymerase chain reaction (PCR)

**Management**

Fever and its associated systemic symptoms can be treated with paracetamol, and by tepid sponging to cool the skin. Replacement of salt and water is important in patients with drenching sweats. Further management is focused on the underlying cause.

#### Fever with localising symptoms or signs

In most patients, the site of infection is apparent after clinical evaluation (p. 216), and the likelihood of infection is reinforced by investigation results (e.g. neutrophilia with raised ESR and CRP in bacterial infections). Not all apparently localising symptoms are reliable, however; headache, breathlessness and diarrhoea can occur in sepsis or malaria without localised infection in the central nervous system (CNS), respiratory tract or gastrointestinal tract, and abdominal pain may be a feature of basal pneumonia. Careful interpretation of the clinical features is vital (e.g. severe headache associated with photophobia, rash and neck stiffness suggests meningitis, whereas moderate headache with cough and rhinorrhea is consistent with a viral upper respiratory tract infection).

Common infections that present with fever are shown in Figure 11.1. Further investigation and management are specific to the cause, but may include empirical antimicrobial therapy (p. 116) pending confirmation of the microbiological diagnosis.

#### Pyrexia of unknown origin

Pyrexia of unknown origin (PUO) was classically defined as a temperature above 38.0°C on multiple occasions for more than 3 weeks, without diagnosis, despite initial investigation in hospital for 1 week. The definition has been relaxed to allow for investigation over 3 days of inpatient care, three outpatient visits or 1 week of intensive ambulatory investigation. Subsets of PUO are described as HIV-1 related, immune-deficient or nosocomial. Up to one-third of cases of PUO remain undiagnosed.

**Clinical assessment**

Major causes of PUO are outlined in Box 11.2. Rare causes, such as periodic fever syndromes (p. 81), should be considered in those with a family history. Children and younger adults are more likely to have infectious causes – in particular, viral infections. Older adults are more likely to have certain infectious and non-infectious causes (see Box 11.1). Detailed history and examination should be repeated at regular intervals to detect emerging features (e.g. rashes, signs of infective endocarditis).
Presenting problems in infectious diseases

- induced sputum or other specimens for mycobacterial stains and culture
- serological tests, including an HIV test, and ferritin estimation
- imaging of the abdomen by ultrasonography or computed tomography (CT)
- echocardiography.

Lesions identified on imaging should usually be biopsied in order to seek evidence of relevant pathogens by culture, histopathology or nucleic acid detection. Particularly in patients who have received prior antimicrobials, 16S rRNA analysis (Box 6.2, p. 101) may aid diagnosis if a microorganism is not cultured. The chance of a successful diagnosis is greatest if procedures for obtaining

(p. 527) or features of vasculitis). In men, the prostate should be considered as a potential source of infection.

Clinicians should be alert to the possibility of factitious fever, in which high temperature recordings are engineered by the patient (Box 11.3).

**Investigations**

If initial investigation of fever is negative, further microbiological and non-microbiological investigations should be considered (Boxes 11.4 and 11.5). As with initial investigation of fever described above, the selection and prioritisation of tests will be influenced by the geographical location of potential exposure to pathogens (Box 11.4). These will usually include:

### 11.3 Clues to the diagnosis of factitious fever

- A patient who looks well
- Bizarre temperature chart with absence of diurnal variation and/or temperature-related changes in pulse rate
- Temperature > 41°C
- Absence of sweating during defervesence
- Normal erythrocyte sedimentation rate and C-reactive protein despite high fever
- Evidence of self-injection or self-harm
- Normal temperature during supervised (observed) measurement
- Infection with multiple commensal organisms (e.g. enteric or mouth flora)

and transporting the correct samples in the appropriate media are carefully planned between the clinical team, the radiologist or surgeon performing the procedure, and the local microbiologist and histopathologist. Positron emission tomography (PET) scans may aid diagnosis of vasculitis or help selection of biopsy sites. Liver biopsy may be justified – for example, to identify idiopathic granulomatous hepatitis – if there are biochemical or radiological abnormalities. Bone marrow biopsies have a diagnostic yield of up to 15%, most often revealing haematological malignancy, myelodysplasia or tuberculosis, and also identifying brucellosis, typhoid fever or visceral leishmaniasis. Bone marrow should be sent for culture, as well as microscopy. Laparoscopy is occasionally undertaken with biopsy of abnormal tissues. Splenic aspiration in specialist centres is the diagnostic test of choice for
11.4 Microbiological investigation of pyrexia of unknown origin

**Location-independent investigations**

<table>
<thead>

</tr>
</tbody>
</table>

**Microscopy**

- Blood for trypanosomiasis, malaria and *Borrelia* spp.
- Stool for geographically restricted ova, cysts and parasites
- Biopsy for light microscopy (dimorphic fungi, *Leishmania* spp. and other parasites)
- Urine for red blood cells and schistosome ova

**Antigen detection**

- Blood, e.g. dengue virus NS1 antigen, *Histoplasma* antigen (restricted availability) and malaria antigen (e.g. HRP-2 for *Plasmodium falciparum* or parasite-specific LDH for *P. falciparum* and *P. vivax*)

**Nucleic acid detection**

- Blood for causes of viral haemorrhagic fever
- CSF for geographically restricted viruses, e.g. Japanese encephalitis virus
- Nasopharyngeal aspirate/throat swab or bronchoalveolar lavage fluid for geographically restricted respiratory viruses, e.g. MERS-CoV

**Immunological tests**

- Serology (antibody detection) for viruses, dimorphic fungi and protozoa

---

1 This list does not apply to every patient with a pyrexia of unknown origin. Appropriate tests should be selected in a stepwise manner, according to specific predisposing factors, epidemiological exposures and local availability, and should be discussed with a microbiologist. 2 Addition of these tests should be guided by the location of presentation or travel history.

11.5 Additional investigations in PUO

- Serological tests for connective tissue disorders:
  - Autoantibody screen
  - Complement levels
  - Immunoglobulins
  - Cryoglobulins
- Ferritin
- Echocardiography
- Ultrasound of abdomen
- CT/MRI of thorax, abdomen and/or brain
- Imaging of the skeletal system:
  - Plain X-rays
  - CT/MRI spine
  - Isotope bone scan
- Labelled white cell scan
- Positron emission tomography (PET)/single-photon emission computed tomography (SPECT)
- Biopsy:
  - Bronchoscopy and lavage ± transbronchial biopsy
  - Lymph node aspirate or biopsy
  - Biopsy of radiological lesion
  - Biopsy of liver
  - Bone marrow aspirate and biopsy
  - Lumbar puncture
  - Laparoscopy and biopsy
  - Temporal artery biopsy
suspected visceral leishmaniasis. Temporal artery biopsy should be considered in patients over the age of 50 years, even in the absence of physical signs or a raised ESR. ‘Blind’ biopsy of other structures in the absence of localising signs or laboratory or radiology results is unhelpful.

**Clinical assessment**

The history should address the following risk factors:
- **Site of injection.** Femoral vein injection is associated with vascular complications such as deep venous thrombosis (50% of which are septic) and accidental arterial injection with false aneurysm formation or a compartment syndrome due to swelling within the fascial sheath. Local complications include ilio-psoas abscess, and septic arthritis of the hip joint or sacroiliac joint. Injection of the jugular vein can be associated with cerebrovascular complications. Subcutaneous and intramuscular injection has been related to infection by clostridial species, the spores of which contaminate heroin. *Clostridium novyi*

**Fever in the injection drug-user**

Intravenous injection of recreational drugs is widespread in many parts of the world (p. 1184). Infective organisms are introduced by non-sterile (often shared) injection equipment (Fig. 11.2). The risks increase with prolonged drug use and injection into large veins of the groin and neck necessitated by progressive thrombosis of superficial peripheral veins. The most common causes of fever are soft tissue or respiratory infections.

---

**Cardiovascular system**
- Systolic ‘V’ waves in JVP of tricuspid regurgitation (p. XXX)
- Regurgitant murmurs in endocarditis

**Respiratory system**
- Consolidation in pneumonia
- Upper lobe signs in tuberculosis
- Pleural rub with septic pulmonary emboli

**Abdomen**
- Jaundice ± tender liver edge with hepatitis
- Pain in left upper quadrant with splenic abscess

**Bone and joints**
- Osteomyelitis
- Septic arthritis

**Injection sites**
- Abscesses
- Fistula
- Haematoma
- Pseudoaneurysm
- Femoral stretch test
- Passive extension of the hip joint causes pain and reflex muscle spasm in ilio-psoas abscess

**Legs**
- Signs of DVT
- Vasculitis or ischaemic signs of septic emboli, endocarditis or vasospasm
- Compartment syndrome

---

**Fig. 11.2 Fever in the injection drug-user: key features of clinical examination.** Full examination (p. 216) is required but features most common amongst injection drug-users are shown here. (DVT = deep venous thrombosis; JVP = jugular venous pulse)
Endocarditis:

- **Tricuspid valve endocarditis** caused by *Staph. aureus* is prevalent in the community, a clinically occult infection more common in injection drug-users.  
- **Septic arthritis** of the knee is common, and may lead to abscess formation.
- **Technical details of injection.** Sharing of needles and other paraphernalia (including spoons and filters) increases the risk of blood-borne virus infection (e.g. HIV-1, hepatitis B or C virus). Some users lubricate their needles by licking them prior to injection, thus introducing mouth organisms (e.g. anaerobic streptococci, *Fusobacterium* spp. and *Prevotella* spp.). Contamination of commercially available lemon juice, used to dissolve heroin before injection, has been associated with blood-stream infection with *Candida* spp.
- **Substances injected.** Injection of cocaine is associated with a variety of vascular complications. Certain formulations of heroin have been linked with particular infections, e.g. wound botulism with black tar heroin. Drugs are often mixed with other substances, e.g. talc.
- **Blood-borne virus status.** Results of previous HIV-1 and hepatitis virus tests or vaccinations for hepatitis viruses should be recorded.
- **Surreptitious use of antimicrobials.** Addicts may use antimicrobials to self-treat infections, masking initial blood culture results.

Key findings on clinical examination are shown in Figure 11.2. It can be difficult to distinguish the effects of infection from the effects of drugs or drug withdrawal (excitement, tachycardia, sweating, marked myalgia, delirium). Stupor and delirium may result from drug administration but may also indicate meningitis or encephalitis. Non-infected venous thromboembolism is also common in this group.

**Investigations**

The initial investigations are as for any fever (see above), including a chest X-ray and blood cultures. Since blood sampling may be difficult, contamination is often a problem. Echocardiography to detect infective endocarditis should be performed in all injection drug-users with bacteraemia due to *Staphylococcus aureus* or other organisms associated with endocarditis (Fig. 11.3A); thromboembolic phenomena; or a new or previously undocumented murmur. Endovascular infection should also be suspected if lung abscesses or pneumatoceles are detected radiologically. Infected thrombus at injection sites, such as the groin, is common, and may lead to abscess formation. Additional imaging should be focused on sites of injection or of localising symptoms and signs (Fig. 11.3B). Any pathological fluid collections should be sampled.

Urinary toxicology tests may suggest a non-infectious cause of the presenting complaint. While being investigated, all injection drug-users should be offered testing for infection with hepatitis B and C virus and HIV-1.

Injection drug-users may have more than one infection. Skin and soft tissue infections are most often due to *Staph. aureus* or streptococci, and sometimes to *Clostridium* spp. or anaerobes. Pulmonary infections are most often due to the common pathogens causing community-acquired pneumonia, tuberculosis or septic emboli (Fig. 11.3C). Endocarditis with septic emboli commonly involves *Staph. aureus* and viridans streptococci, but *Pseudomonas aeruginosa* and *Candida* spp. are also encountered.

**Management**

Empirical therapy of fever in the injection drug-user includes an antistaphylococcal penicillin (e.g. flucloxacillin) or, if meticillin-resistant *Staph. aureus* (MRSA) is prevalent in the community, a glycopeptide (e.g. vancomycin) or lipopeptide (e.g. daptomycin). Once microbiological results are available, therapy can be narrowed to focus on the microorganism identified. In injection drug-users, meticillin-sensitive *Staph. aureus* is customarily treated with high-dose intravenous flucloxacillin, with shorter durations for uncomplicated right-sided endocarditis. Right-sided endocarditis caused by MRSA is usually treated with 4 weeks of vancomycin plus gentamicin for the first week. Specialist advice should be sought.

For localised infections of the skin and soft tissues, oral therapy with agents active against staphylococci, streptococci and anaerobes is appropriate (e.g. flucloxacillin plus co-amoxiclav or clindamycin). Non-adherence to prescribed antimicrobial regimens leads to a high rate of complications.

**Fever in the immunocompromised host**

Immunocompromised hosts include those with congenital immunodeficiency (p. 77), HIV infection (Ch. 12) and iatrogenic
immunosuppression induced by chemotherapy (p. 1330), transplantation (p. 88) or immunosuppressant medicines, including high-dose glucocorticoids. Metabolic abnormalities, such as under-nutrition or hyperglycaemia, may also contribute. Multiple elements of the immune system are potentially compromised. A patient may have impaired neutrophil function from chemotherapy, impaired T-cell and/or B-cell responses due to underlying malignancy, T-cell and phagocytosis defects due to glucocorticoids, mucositis from chemotherapy and an impaired skin barrier due to insertion of a central venous catheter.

Fever may result from infectious or non-infectious causes, including drugs, vasculitis, neoplasm, lymphoproliferative disease, graft-versus-host disease (in recipients of haematopoietic stem cell transplants (HSCT); p. 936), organising pneumonitis or Sweet’s syndrome (reddish nodules or plaques with fever and leucocytosis, in association with haematological malignancy).

**Clinical assessment**

The following should be addressed in the history:
- Identification of the immunosuppressant factors and nature of the immune defect.
- Any past infections and their treatment. Infections may recur and antimicrobial resistance may have been acquired in response to prior therapy.
- Exposure to infections, including opportunistic infections that would not cause disease in an immunocompetent host.
- Prophylactic medicines and vaccinations administered.

Examination should include inspection of the normal physical barriers provided by skin and mucosal surfaces and, in particular, central venous catheters, the mouth, sinuses, ears and perianal area (digital rectal examination should be avoided). Disseminated infections can manifest as cutaneous lesions. The areas around fingernails and toenails should also be inspected closely.

**Investigations**

Initial screening tests are as described above (p. 218). Immunocompromised hosts often have decreased inflammatory responses leading to attenuation of physical signs, such as neck stiffness with meningitis, radiological features and laboratory findings, such as leucocytosis. Chest CT scan should be considered in addition to chest X-ray when respiratory symptoms occur. Abdominal imaging may also be warranted, particularly if there is right lower quadrant pain, which may indicate typhilitis (inflammation of the caecum) in neutropenic patients. Blood cultures from a central venous catheter, urine cultures, and stool cultures if diarrhoea is present, and investigation should include fungal stains. Useful molecular techniques include PCR for cytomegalovirus (CMV) and *Aspergillus* spp. DNA, and antigen assays (e.g. cryptococcal antigen (CrAg) for Cryptococcus neoformans, galactomannan for *Aspergillus* spp. in blood, and (1,3)-β-D-glucan for *Aspergillus* spp. and other causes of invasive fungal infection (though this will not identify mucoraceous moulds) or *Legionella pneumophila* type 1 in urine). Antibody detection is rarely useful in immunocompromised patients. Patients with respiratory signs or symptoms should be considered for bronchoalveolar lavage to detect *Pneumocystis jirovecii*, other fungi, bacteria and viruses.

**Neutropenic fever**

Neutropenic fever is defined as a neutrophil count of less than 0.5 x 10^9/L (p. 925) and a single axillary temperature above 38.5°C or three recordings above 38.0°C over a 12-hour period, although the infection risk increases progressively as the neutrophil count drops below 1.0 x 10^9/L. Patients with neutropenia are particularly prone to bacterial and fungal infection. Gram-positive organisms are the most common pathogens, particularly in association with in-dwelling catheters.

Empirical broad-spectrum antimicrobial therapy is commenced as soon as neutropenic fever occurs and cultures have been obtained. The most common regimens for neutropenic sepsis are broad-spectrum penicillins, such as piperacillin–tazobactam IV. The routine addition of aminoglycosides to these agents is not supported by trial data. If fever has not resolved after 3–5 days, empirical antifungal therapy (e.g. caspofungin) is added (p. 125). An alternative antifungal strategy is to use azole prophylaxis in high-risk patients and markers of early fungal infection, such as galactomannan and/or fungal PCR, to guide initiation of antifungal treatment (a ‘pre-emptive approach’).

**Post-transplantation fever**

Fever in transplant recipients may be due to infection, episodes of graft rejection in solid organ transplant recipients, or graft-versus-host disease following HSCT (p. 936).

Infections in solid organ transplant recipients are grouped according to the time of onset (Box 11.6). Those in the first month are mostly related to the underlying condition or surgical complications. Those occurring 1–6 months after transplantation are characteristic of impaired T-cell function. Risk factors for CMV infection have been identified; patients commonly receive either prophylaxis or intensive monitoring involving regular testing for CMV DNA by PCR and early initiation of anti-CMV therapy using intravenous ganciclovir or oral valganciclovir if tests become positive.

Following HSCT, infections in the first 4 weeks are more common in patients receiving a myeloablative-conditioning

</tbody>
</table>

(CMV = cytomegalovirus; HSV = herpes simplex virus; PTLD = post-transplant lymphoproliferative disorder)
regimen (Box 11.6). Later infections are more common if an allogeneic procedure is performed.

Post-transplant lymphoproliferative disorder (PTLD) is an Epstein–Barr virus (EBV)-associated lymphoma that can complicate transplantation, particularly when primary EBV infection occurs after transplantation.

**Positive blood culture**

Blood-stream infection (BSI) is a frequent presentation of infection. This can be community-acquired or hospital-acquired (‘nosocomial’). The most common causes are shown in Box 11.7. In immunocompromised hosts, a wider range of microorganisms may be isolated, e.g. fungi in neutropenic hosts.

Primary BSI describes the situation in which there is no known extravascular source of infection (e.g. pneumonia or urinary tract infection), and is more common in *Staph. aureus* BSI. In community-acquired *Staph. aureus* bacteraemia, 20–30% of cases are associated with infectious endocarditis and up to 10% are due to osteomyelitis. Peripheral and central venous catheters are an important source of nosocomial BSI.

BSI has an associated mortality of 15–40%, depending on the setting, host and microbial factors.

**Clinical assessment**

The history should determine the setting in which BSI has occurred. Host factors predisposing to infection include skin disease, diabetes mellitus, injection drug use, the presence of a central venous, urinary or haemodialysis catheter, and surgical procedures, especially those involving the implantation of prosthetic materials (in particular, endovascular prostheses).

Physical examination should focus on signs of endocarditis (p. 527), evidence of bone or joint infection (tenderness or restriction of movement), and abdominal or flank tenderness. Central venous catheters should be examined for erythema or purulence at the exit site. Particularly in cases with *Candida* spp. infection or suspected infectious endocarditis, fundoscopy after pupil dilatation should be performed.

**Investigations**

Positive blood cultures may be caused by contaminants. When isolated from only one bottle, or from all bottles from one venesection, coagulase-negative staphylococci often represent contamination. Repeated isolation of this organism, however, should raise suspicion of infective endocarditis or, in a patient with any form of prosthetic material, prosthetic infection. *Viridans streptococci* occasionally cause transient non-significant bacteraemia or blood culture contamination but, in view of their association with infective endocarditis, significant infection must always be excluded. *Bacillus* spp. (‘aerobic spore bearers’) and *Clostridium* spp. often represent incidental transient bacteraemia or contamination, but certain species (e.g. *C. septicum*) are more likely to be genuine pathogens.

Further investigations are influenced by the causative organism and setting. Initial screening tests are similar to those for fever (p. 218) and should include chest X-ray, urine culture and, in many cases, ultrasound or other imaging of the abdomen. Imaging should also include any areas of bone or joint pain and any prosthetic material, e.g. a prosthetic joint or an aortic graft.

Echocardiography should be considered for those patients with BSI who have valvular heart disease or clinical features of endocarditis (p. 527), those whose cultures reveal an organism that is a common cause of endocarditis (e.g. *Staph. aureus*, *viridans streptococci* or enterococci), those in whom multiple blood cultures are positive for the same organism, and those with a rapid positive result on culture. The sensitivities of transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) for the detection of vegetations are 50–90% and over 95%, respectively. Therefore, if TTE is negative, TOE should be performed.

Certain rare causes of BSI have specific associations that warrant further investigation. Endocarditis caused by *Streptococcus galolyticus* subsp. *galolyticus* (formerly *Strep. bovis* biotype I) and BSI with *C. septicum* are both associated with colonic carcinoma and their isolation is an indication for colonoscopy.

**Management**

BSI requires antimicrobial therapy and attention to the source of infection, including surgical drainage if appropriate. Two weeks of therapy may be sufficient for *Staph. aureus* BSI from central and peripheral venous catheter infections when the source is identified and removed, for uncomplicated skin and soft tissue infections, and for uncomplicated right-sided infective endocarditis. Other *Staph. aureus* BSIs are usually treated for 4–6 weeks.

### 11.7 Common causes of blood-stream infection

<tr>
<td><em>Candida spp.</em></td>
<td><em>Candida spp.</em></td>
</tr>
</tbody>
</table>

(MRSA = meticillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant enterococci)

**Central venous catheter infections**

Infections of central venous catheters typically involve the catheter lumen and are associated with fever, positive blood cultures and, in some cases, signs of purulence or exudate at the site of insertion. Infection is more common in temporary catheters inserted into the groin or jugular vein than in those in the subclavian vein. Tunnelled catheters, e.g. Hickman catheters, may also develop tunnel site infections.

Staphylococci account for 70–90% of catheter infections, with coagulase-negative staphylococci more common than *Staph. aureus*. Other causes include enterococci and Gram-negative bacilli. Unusual Gram-negative organisms, such as *Citrobacter freundii* and *Pseudomonas aeruginosa*, raise the possibility of non-sterile infusion equipment or infusate. *Candida* spp. are a common cause of line infections, particularly in association with total parenteral nutrition. Non-tuberculous mycobacteria may cause tunnel infections.

**Investigations and management**

In bacteraemic patients with fever and no other obvious source of infection, a catheter infection is likely. Local evidence of erythema, purulence or thrombophlebitis supports the diagnosis. However, microbiological confirmation is essential (p. 106). Catheter-related infection is suggested by higher colony counts.
or shorter time to positivity in blood cultures obtained through the catheter than in peripheral blood cultures. If the line is removed, a semi-quantitative culture of the tip may confirm the presence of 15 or more colony-forming units, but this is retrospective and does not detect luminal infection.

For coagulase-negative staphylococcal line infections, the options are to remove the line and provide 5–7 days’ therapy or, particularly in the case of tunnelled catheters, to treat empirically with a glycopeptide antibiotic, e.g. vancomycin, with or without the use of antibiotic-containing lock therapy to the catheter for approximately 14 days. For *Staph. aureus* infection, the chance of curing an infection with the catheter in situ is low and the risks from infection are high. Therefore, unless the risks of catheter removal outweigh the benefits, treatment involves catheter removal, followed by 14 days of antimicrobial therapy; the same applies to infections with *Pseudomonas aeruginosa*, *Candida* spp., atypical mycobacteria or *Bacillus* spp. Infections complicated by endocarditis, thrombophlebitis, metastatic infection or tunnel infection also require catheter removal.

Infection prevention is a key component of the management of vascular catheters. Measures include strict attention to hand hygiene, optimal stitting, full aseptic technique on insertion and subsequent interventions, skin antisepsis with chlorhexidine and isopropyl alcohol, daily assessment of catheter sites (e.g. with visual infusion phlebitis (VIP) score; see Box 11.37, p. 251), and daily consideration of the continuing requirement for catheterisation. The use of catheters impregnated with antifungals, such as chlorhexidine or silver, is advocated in some settings.

### Sepsis

Sepsis is discussed on page 196 and there are many causes (Box 11.8). The results of blood cultures and pre-existing host factors guide initial investigations. Patients who are immunocompromised may have a broader range of causal pathogens that may be harder to culture, including mycobacteria and fungi. In many regions, malaria and dengue must also be excluded.

#### Severe skin and soft tissue infections

Skin and soft tissue infections (SSTIs) are an important cause of sepsis. Cases can be classified as in Box 11.9, according to the clinical features and microbiological findings. In some cases, severe systemic features may be out of keeping with mild local features.

##### Necrotising fasciitis

In necrotising fasciitis, cutaneous erythema and oedema progress to bullae or areas of necrosis. Unlike in cellulitis, pain may be disproportionately intense in relation to the visible cutaneous features or may spread beyond the zone of erythema. The infection spreads quickly along the fascial plane. Type 1 necrotising fasciitis is a mixed infection with Gram-negative bacteria and anaerobes, often seen post-operatively in diabetic or immunocompromised hosts. Subcutaneous gas may be present. Type 2 necrotising fasciitis is caused by group A or other streptococci. Approximately 60% of cases are associated with streptococcal toxic shock syndrome (p. 253). Type 3 infection...
involves organisms such as *Aeromonas hydrophila* and *Vibrio vulnificus*, which is found in tropical to subtropical regions and is associated with marine exposure. Type 4 is caused by fungi such as mucoraceous moulds and may also occur geographically in incidence with recent reports of increased cases in India and other regions.

Necrotising fasciitis is a medical emergency, requiring immediate surgical débridement with inspection of the involved muscle groups, in addition to antimicrobial therapy (Fig. 11.4). Empirical treatment is with broad-spectrum agents (e.g. piperacillin–tazobactam plus clindamycin; meropenem with clindamycin). Cefazidime or ciprofloxacin with doxycycline may be used where marine exposure is a factor, and antifungals for suspected fungal necrotising fasciitis, but it is important to combine these with effective coverage against streptococcal infection. MRSA-associated necrotising fasciitis has emerged in some regions and in these places appropriate therapy for MRSA, such as a glycopeptide or linezolid, should be added to the empirical regimen until microbiological results allow narrowing of the antimicrobial spectrum. Hyperbaric oxygen therapy may be considered for polymicrobial infection. Group A streptococcal infection is treated with benzylpenicillin plus clindamycin, and often immunoglobulin, though to date clinical trials have not provided clear evidence of the benefit of immunoglobulin.

**Gas gangrene**

Although *Clostridium* spp. may colonise or contaminate wounds, no action is required unless there is evidence of spreading infection. Infection may be limited to tissue that is already damaged (anaerobic cellulitis) or may involve healthy muscle (gangrene).

In anaerobic cellulitis, usually due to *C. perfringens* or other clostridia infecting devitalised tissue following a wound, gas forms locally and extends along tissue planes but bacteraemia does not occur. Prompt surgical débridement of devitalised tissue and therapy with penicillin or clindamycin is usually effective.

Gas gangrene (clostridial myonecrosis) is defined as acute invasion of healthy living muscle undamaged by previous trauma, and is most commonly caused by *C. perfringens*. In at least 70% of cases, it follows deep penetrating injury sufficient to create an anaerobic (ischaemic) environment and allow clostridial introduction and proliferation. Severe pain at the site of the injury progresses rapidly over 18–24 hours. Skin colour changes from palor to bronze/purple discoloration and the skin is tense, swollen, oedematous and exquisitely tender. Gas in tissues may be obvious, with crepitus on clinical examination, or visible on X-ray, CT or ultrasound. Signs of systemic toxicity develop rapidly, with high leucocytosis, multi-organ dysfunction, raised creatine kinase and evidence of disseminated intravascular coagulation and haemolysis. Antibiotic therapy with high-dose intravenous penicillin and clindamycin is recommended, coupled with aggressive surgical débridement of the affected tissues. Alternative agents include cephalosporins and metronidazole. Hyperbaric oxygen has a putative but controversial role.

**Other SSTIs**

‘Synergistic gangrene’ is a polymicrobial infection with anaerobes and other bacteria (*Staph. aureus* or Gram-negatives). When this affects the genital/perineal area, it is known as ‘Fournier’s gangrene’. Severe gangrenous cellulitis in immunocompromised hosts may involve Gram-negative bacteria or fungi. *Entamoeba histolytica* can cause soft tissue necrosis following abdominal surgery in areas of the world where infection is common. Contact with sea water or shellfish consumption in tropical to subtropical regions worldwide, such as the Gulf of Mexico, can lead to infection with *Vibrio vulnificus*. This infection causes soft tissue necrosis and bullae, and may lead to necrotising fasciitis. Patients with chronic liver disease are particularly susceptible to this infection and can develop sepsis.

**Acute diarrhoea and vomiting**

Acute diarrhoea (p. 783), sometimes with vomiting, is the predominant symptom in infective gastroenteritis (Box 11.10). Acute diarrhoea may also be a symptom of other infectious and non-infectious diseases (Box 11.11). Stress, whether psychological or physical, can also produce loose stools.

The World Health Organisation (WHO) estimates that there are more than 1.7 billion cases of acute diarrhoea annually globally, with 760 000 deaths in children under 5. In developed countries, diarrhoea remains an important problem, with the elderly being most vulnerable (Box 11.12). The majority of episodes are due to infections spread by the faecal–oral route and transmitted either on fomites, on contaminated hands, or in food or water. Measures such as the provision of clean drinking water, appropriate disposal of human and animal sewage, and the application of simple principles of food hygiene can all limit gastroenteritis.

The clinical features of food-borne gastroenteritis vary. Some organisms (*Bacillus cereus, Staph. aureus* and *Vibrio cholerae*) elute exotoxins that cause vomiting and/or so-called ‘secretory’ diarrhoea (watery diarrhoea without blood or faecal leucocytes,
11.10 Causes of infectious gastroenteritis

Toxin in food: <6 hrs incubation
- Bacillus cereus (p. 262)
- Staphylococcus aureus (p. 262)
- Clostridium spp. enterotoxin (p. 262)

Bacterial: 12–72 hrs incubation
- Enterotoxigenic Escherichia coli (ETEC, p. 263)*
- Shiga toxin-producing E. coli (EHEC, p. 263)*
- Enteroinvasive E. coli (EIEC, p. 265)*
- Vibrio cholerae (p. 264)
- Salmonella (p. 262)
- Shigella* (p. 265)
- Campylobacter* (p. 262)
- Clostridium difficile* (p. 264)

Viral: short incubation
- Rotavirus (p. 249)
- Norovirus (p. 249)

Protozoal: long incubation

- Cystoisosporiasis (p. 233)

*Associated with bloody diarrhoea.

11.11 Differential diagnosis of acute diarrhoea and vomiting

Infectious causes
- Gastroenteritis
- Clostridium difficile infection (p. 264)
- Acute diverticulitis (p. 833)
- Sepsis (p. 196)
- Pelvic inflammatory disease (p. 836)
- Meningococcaemia (p. 1119)
- Pneumonia (especially ‘atypical disease’, p. 582)
- Malaria (p. 273)

Non-infectious causes

Gastrointestinal
- Inflammatory bowel disease (p. 813)
- Bowel malignancy (p. 827)
- Overflow from constipation (p. 834)
- Enteral tube feeding

Metabolic
- Diabetic ketoacidosis (p. 735)
- Thyrotoxicosis (p. 635)
- Uraemia (p. 414)
- Neuro-endocrine tumours releasing (e.g.) VIP or 5-HT

Drugs and toxins
- NSAIDs
- Cytotoxic agents
- Antibiotics
- Proton pump inhibitors
- Diogflagellates (p. 149)
- Plant toxins (p. 150)
- Heavy metals
- Ciguatera fish poisoning (p. 149)
- Scombrototoxic fish poisoning (p. 150)

*(5-HT = 5-hydroxytryptamine, serotonin; NSAIDs = non-steroidal anti-inflammatory drugs; VIP = vasoactive intestinal peptide)

11.12 Infectious diarrhoea in old age

- Incidence: not increased but the impact is greater.
- Mortality: most deaths due to gastroenteritis in the developed world are in adults aged over 70. Most are presumed to be caused by dehydration leading to organ failure.
- Clostridium difficile infection (CDI): more common, especially in hospital and nursing home settings, usually following antibiotic exposure.

11.13 Foods associated with infectious illness, including gastroenteritis

Raw seafood
- Norovirus
- Vibrio spp.
- Hepatitis A

Raw eggs
- Salmonella serovars
- Hepatitis E (pork products)

Undercooked meat or poultry
- Salmonella serovars
- Campylobacter spp.
- EHEC
- Clostridium perfringens

Unpasteurised milk or juice
- Salmonella serovars
- Campylobacter spp.
- EHEC
- Yersinia enterocolitica

Unpasteurised soft cheeses
- Salmonella serovars
- Campylobacter spp.
- ETEC
- Yersinia enterocolitica
- Listeria monocytogenes

Home-made canned goods
- Clostridium botulinum

Raw hot dogs, pâté
- Listeria monocytogenes

(EHEC = enterohaemorrhagic Escherichia coli; ETEC = enterotoxigenic E. coli)
infection, particularly if the clinical features suggest a syndrome other than gastroenteritis.

Management

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and to establish whether other linked cases exist (p. 114).

Fluid replacement

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Although normal daily fluid intake in an adult is only 1–2 L, there is considerable additional fluid movement in and out of the gut in secretions (see Fig. 21.7, p. 769). Altered gut resorption with diarrhoea can result in substantial fluid loss; for example, 10–20 L of fluid may be lost in 24 hours in cholera. The fluid lost in diarrhoea is isotonic, so both water and electrolytes need to be replaced. Absorption of electrolytes from the gut is an active process requiring energy. Infected mucosa is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 11.14). ORS can be just as effective as intravenous replacement fluid, even in the management of cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and, if possible, continue normal dietary food intake. If this is impossible – due to vomiting, for example – intravenous fluid administration will be required. In very sick patients or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations:

- **Replacement of established deficit.** After 48 hours of moderate diarrhoea (6–10 stools per 24 hrs), the average adult will be 2–4 L depleted from diarrhoea alone. Associated vomiting will compound this. Adults with this symptomatology should therefore be given rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation. Longer symptomatology or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention.

The severity of diarrhoea may be assessed by reference to the Bristol stool form scale (Bristol stool chart), which allows an objective assessment of stool consistency by providing a verbal and visual reference scale (Fig. 11.5). The Bristol stool form scale was developed in the 1990s to monitor patients with irritable bowel syndrome, but its main use (at least in UK hospitals) is to monitor hospital inpatients with loose stool to assist in decisions on stool sampling and infection prevention precautions, especially in relation to *C. difficile*.

**Investigations**

These include stool inspection for blood and microscopy for leucocytes, and also an examination for ova, cysts and parasites if the history indicates residence or travel to areas where these infections are prevalent. Stool culture should be performed and *C. difficile* toxin sought. FBC and serum electrolytes indicate the degree of inflammation and dehydration. Where choler is prevalent, examination of a wet film with dark-field microscopy for darting motility may provide a diagnosis. In a malarious area, a blood film for malaria parasites should be obtained. Blood and urine cultures and a chest X-ray may identify alternative sites of infection, particularly if the clinical features suggest a syndrome other than gastroenteritis.

**Management**

All patients with acute, potentially infective diarrhoea should be appropriately isolated to minimise person-to-person spread of infection. If the history suggests a food-borne source, public health measures must be implemented to identify the source and to establish whether other linked cases exist (p. 114).

**Fluid replacement**

Replacement of fluid losses in diarrhoeal illness is crucial and may be life-saving.

Although normal daily fluid intake in an adult is only 1–2 L, there is considerable additional fluid movement in and out of the gut in secretions (see Fig. 21.7, p. 769). Altered gut resorption with diarrhoea can result in substantial fluid loss; for example, 10–20 L of fluid may be lost in 24 hours in cholera. The fluid lost in diarrhoea is isotonic, so both water and electrolytes need to be replaced. Absorption of electrolytes from the gut is an active process requiring energy. Infected mucosa is capable of very rapid fluid and electrolyte transport if carbohydrate is available as an energy source. Oral rehydration solutions (ORS) therefore contain sugars, as well as water and electrolytes (Box 11.14). ORS can be just as effective as intravenous replacement fluid, even in the management of cholera. In mild to moderate gastroenteritis, adults should be encouraged to drink fluids and, if possible, continue normal dietary food intake. If this is impossible – due to vomiting, for example – intravenous fluid administration will be required. In very sick patients or those with cardiac or renal disease, monitoring of urine output and central venous pressure may be necessary.

The volume of fluid replacement required should be estimated based on the following considerations:

- **Replacement of established deficit.** After 48 hours of moderate diarrhoea (6–10 stools per 24 hrs), the average adult will be 2–4 L depleted from diarrhoea alone. Associated vomiting will compound this. Adults with this symptomatology should therefore be given rapid replacement of 1–1.5 L, either orally (ORS) or by intravenous infusion (normal saline), within the first 2–4 hours of presentation. Longer symptomatology or more persistent/severe diarrhoea rapidly produces fluid losses comparable to diabetic ketoacidosis and is a metabolic emergency requiring active intervention.

*Values given in mmol/L for electrolyte and kcal/L for energy components. (WHO = World Health Organisation)*
• Replacement of ongoing losses. The average adult’s diarrhoeal stool accounts for a loss of 200 mL of isotonic fluid. Stool losses should be carefully charted and an estimate of ongoing replacement fluid calculated. Commercially available rehydration sachets are conveniently produced to provide 200 mL of ORS; one sachet per diarrhoea stool is an appropriate estimate of supplementary replacement requirements.

• Replacement of normal daily requirement. The average adult has a daily requirement of 1–1.5 L of fluid in addition to the calculations above. This will be increased substantially in fever or a hot environment.

Antimicrobial agents

In non-specific gastroenteritis, routine use of antimicrobials does not improve outcome and may lead to antimicrobial resistance or side-effects. They are usually used where there is systemic involvement, a host with immunocompromise or significant comorbidity.

Evidence suggests that, in EHEC infections, the use of antibiotics may make the complication of haemolytic uraemic syndrome (HUS; p. 408) more likely due to increased toxin release. Antibiotics should therefore not be used in this condition.

Conversely, antibiotics are indicated in *Shigella dysenteriae* infection and in invasive salmonellosis – in particular, typhoid fever. Antibiotics may also be advantageous in cholera epidemics, reducing infectivity and controlling the spread of infection.

Antidiarrhoeal, antimotility and antisecretory agents

These agents are not usually recommended in acute infective diarrhoea. Loperamide, diphenoxylate and opiates are potentially dangerous in dysentery in childhood, causing intussusception. Antisecretory agents, such as bismuth and chlorpromazine, may make the stools appear more bulky but do not reduce stool fluid losses and may cause significant sedation. Adsorbents, such as kaolin or charcoal, have little effect.

## Non-infectious causes of food poisoning

While acute food poisoning and gastroenteritis are most frequently caused by infections, non-infectious causes must also be considered in the differential diagnosis. These are discussed on page 149.

## Antimicrobial-associated diarrhoea

Antimicrobial-associated diarrhoea (AAD) is a common complication of antimicrobial therapy, especially with broad-spectrum agents. It is most common in the elderly but can occur at all ages. Although the specific mechanism is unknown in most cases of AAD, *C. difficile* (p. 264) is implicated in 20–25% of cases and is the most common cause among patients with evidence of colitis. *C. perfringens* is a rarer cause that usually remains undiagnosed, and *Klebsiella oxytoca* may also cause antibiotic-associated haemorrhagic colitis.

### Infections acquired in the tropics

Recent decades have seen unprecedented increases in long-distance business and holiday travel, as well as extensive migration. Although certain diseases retain their relatively fixed geographical distribution, being dependent on specific vectors or weather conditions, many travel with their human hosts and some may then be transmitted to other people. This means that the pattern of infectious diseases seen in each country changes constantly, and travel history and information on countries previously lived in, particularly during childhood, are crucial.

In general, the diversity of infectious diseases is greater in tropical than in temperate countries, and people in temperate countries have immunity to a narrower range of infections, reflecting less exposure in childhood and less ongoing boosting of immunity later in life, so that the most common travel-associated infections are those that are acquired by residents of temperate countries during visits to the tropics. In addition, those who have lived in tropical areas may lose immunity when they move to temperate countries and become susceptible when visiting their homeland.

Most travel-associated infections can be prevented. Pre-travel advice is tailored to the destination and the traveller (Box 11.15). It includes avoidance of insect bites (using at least 20% diethyltoluamide (DEET)), sun protection (sunscreen with a sun protection factor (SPF) of at least 15), food and water hygiene (‘Boil it, cook it, peel it or forget it!’), how to respond to travellers’ diarrhoea (seek medical advice if bloody or if it lasts more than 48 hrs) and, if relevant, safe sex (condom use).

### Fever acquired in the tropics

Presentation with unexplained fever is common in travellers who are visiting or have recently travelled to tropical areas. Fever may also occur in those living in tropical regions if they have not developed immunity to the endemic pathogen or if this immunity is compromised by factors such as pregnancy. Frequent final diagnoses in such patients are malaria, typhoid fever, viral hepatitis and dengue fever. Travellers to affected areas may have viral haemorrhagic fevers (VHFs) such as Ebola, Lassa, Crimean–Congo and Marburg (see Box 11.36, p. 245), avian influenza (H5N1) or Middle East respiratory syndrome (MERS), which require special isolation precautions.

### Clinical assessment

The approach to unexplained fever is as described above and key questions relating to infections acquired in tropical regions are listed in Box 11.16. Medicines purchased in some countries may have reduced efficacy, e.g. for malaria prophylaxis. Consult reliable up-to-date sources about resistance to antimalarial drugs

---

*Further information is available at fitfortravel.nhs.uk.*
in the country visited. Vaccinations against yellow fever and hepatitis A and B are sufficiently effective to virtually exclude these infections. Oral and injectable typhoid vaccinations are 70–90% effective.

The differential diagnosis is guided by the clinical scenario, presence of specific exposures (Box 11.17) and incubation period (Box 11.18). Falciparum malaria tends to present between 7 and 28 days after exposure in an endemic area. VHF, dengue and rickettsial infection can usually be excluded if more than 21 days have passed between leaving the area and onset of illness.

**Fig. 11.6** Approach to the patient with suspected viral haemorrhagic fever (VHF). See page 245. *Epidemiological risk factors: staying with a febrile individual, caring for a sick individual, or contact with body fluids from a suspected human or animal case of VHF. (PCR = polymerase chain reaction)
Clinical examination is summarised on page 216. Particular attention should be paid to the skin, throat, eyes, nail beds, lymph nodes, abdomen and heart. Patients may be unaware of tick bites or eschars (p. 270). Body temperature should be measured at least twice daily.

**Investigations and management**

Initial investigations should start with blood films for malaria parasites, FBC, urinalysis and chest X-ray if indicated. Box 11.19 lists diagnoses and investigations to consider in unexplained acute fever.

Management is directed at the underlying cause. In patients with suspected VHF (p. 245), strict infection control measures with isolation and barrier nursing are implemented to prevent contact with the patient’s body fluids. The risk of VHF should be determined using epidemiological risk factors and clinical signs (Fig. 11.6), and further management undertaken as described on page 246.

**Diarrhoea acquired in the tropics**

Gastrointestinal illness is the most common infection amongst visitors to the tropics, with Salmonella spp., Campylobacter spp. and Cryptosporidium spp. infections prevalent worldwide (Box 11.20). Shigella spp. and Entamoeba histolytica (amoebiasis) are usually encountered in visitors to or residents of the Indian subcontinent or sub-Saharan and southern Africa.

The approach to patients with acute diarrhoea is described on page 227. The benefits of treating travellers’ diarrhoea with antimicrobials are marginal, with slight reductions in stool

**Most common causes of travellers’ diarrhoea**

- Enterotoxigenic E. coli (ETEC)
- Shigella spp.
- Campylobacter jejuni
- Salmonella serovars
- Plesiomonas shigelloides
- Non-cholera Vibrio spp.
- Aeromonas spp.
Eosinophilia acquired in the tropics

Eosinophilia occurs in a variety of haematological, allergic and inflammatory conditions discussed on page 927. It may also arise in HIV-1 and human T-cell lymphotropic virus (HTLV)-1 infection. However, eosinophils are important in the immune response to parasitic infections, in particular those involving parasites with a tissue migration phase. In the context of travel to or residence in the tropics, a patient with an eosinophil count of more than 0.4 × 10^9/L should be investigated for both non-parasitic (see Box 23.9, p. 926) and parasitic causes (Box 11.22).

The response to parasite infections is often different when travellers to and residents of endemic areas are compared. Travellers often have recent and light infections associated with eosinophilia. Residents have often been infected for a long time, have evidence of chronic pathology and no longer have eosinophilia.

Clinical assessment

A history of travel to known endemic areas for schistosomiasis, onchocerciasis and the filariases will indicate possible causes. Assessment should establish how long patients have spent in endemic areas and the history should address all the elements in Box 11.16.

Physical signs or symptoms that suggest a parasitic cause for eosinophilia include transient rashes (schistosomiasis or strongyloidiasis), fever (Katayama syndrome; p. 295), pruritus (onchocerciasis) or migrating subcutaneous swellings (loiasis, gnathostomiasis) (see Box 11.22). Paragonimiasis can give rise to haemoptysis, and the migratory phase of intestinal nematodes or lymphatic filariasis may cause cough, wheezing and transient pulmonary infiltrates. Schistosomiasis, strongyloidiasis and gnathostomiasis induce transient respiratory symptoms with infiltrates in the acute stages and, when eggs reach the pulmonary vasculature in chronic schistosomiasis infection, can

</table>
result in shortness of breath with features of right heart failure due to pulmonary hypertension. Fever and hepatosplenomegaly are seen in schistosomiasis, Fasciola hepatica infection and toxocariasis (visceral larva migrans). Intestinal worms, such as Ascaris lumbricoides and Strongyloides stercoralis, can cause abdominal symptoms, including intestinal obstruction and diarrhoea. In the case of heavy infestation with Ascaris, this may be due to fat malabsorption and there may be associated nutritional deficits. Schistosoma haematobium can cause haematuria or haematospermia. Toxocara spp. can give rise to choroidal lesions with visual field defects. Angiostrongylus cantonensis and gnathostomiasis induce eosinophilic meningitis, and the hyperinfection syndrome caused by S. stercoralis in immunocompromised hosts induces meningitis due to Gram-negative bacteria. Myositis is a feature of trichinosis (trichinellosis) and cysticercosis, while periorbital oedema is found in trichinosis.

**Investigations**

The diagnosis of a parasitic infestation requires direct visualisation of adult worms, larvae or ova. Serum antibody detection may not distinguish between active and past infection and is often unhelpful in those born in endemic areas. Radiological investigations may provide circumstantial evidence of parasite infestation. Box 11.23 describes initial investigations for eosinophilia.

**Management**

A specific diagnosis guides therapy. In the absence of a specific diagnosis, many clinicians will give an empirical course of praziquantel if the individual has potentially been exposed to schistosomiasis, or with albendazole/vermectin if strongyloidiasis or intestinal nematodes are likely causes.

### Skin conditions acquired in the tropics

Community-based studies in the tropics consistently show that skin infections (bacterial and fungal), scabies and eczema are the most common skin problems (Box 11.24). Scabies and eczema are discussed on pages 1241 and 1244. Cutaneous leishmaniasis and onchocerciasis have defined geographical distributions (pp. 284 and 292). In travellers, secondarily infected insect bites, pyoderma, cutaneous larva migrans and non-specific dermatitis are common.

During the investigation of skin lesions, enquiry should be made about habitation, activities undertaken and regions visited (see Box 11.16). Examples of skin lesions in tropical disease are shown in Figure 11.7.

Skin biopsies are helpful in diagnosing aetiology. Culture of biopsy material may be needed to diagnose bacterial, fungal, parasitic and mycobacterial infections.

### Infections in adolescence

Particular issues of relevance in adolescent patients are shown in Box 11.25.

### Infections in pregnancy

Box 11.26 shows some of the infections encountered in pregnancy.
Presenting problems in infectious diseases

11.2.5 Key issues in infectious diseases in adolescence

- **Common infectious syndromes**: infectious mononucleosis, bacterial pharyngitis, whooping cough, pneumonia, staphylococcal skin/soft tissue infections, urinary tract infections, acute gastroenteritis.
- **Life-threatening infections**: meningococcal infection (sepsis and/or meningitis).
- **Sexually transmitted infections**: human papillomavirus (HPV), HIV-1, hepatitis B virus and chlamydia. These may reflect either voluntary sexual activity or sexual coercion/abuse.
- **Travel-related infections**: diarrhoea, malaria etc. are relatively common.
- **Infections in susceptible groups**: patients with cystic fibrosis, congenital immunodeficiency, acute leukaemia and other adolescent malignancies are vulnerable to specific groups of infections.
- **Infections requiring prolonged antimicrobial use**: adherence to chronic therapy is challenging, for both oral (antituberculous or antiretroviral) and systemic (osteomyelitis, septic arthritis or post-operative infections) treatments. Outpatient antimicrobial therapy is preferred to minimise hospitalisation.
- **Vaccination**: engagement with age-specific vaccine programmes should be ensured, e.g. HPV, childhood booster vaccines and meningococcal vaccine.
- **Risk reduction**: education relating to sexual health and alcohol and recreational drug usage is important.

Viral infections

Systemic viral infections with exanthem

Childhood exanthems are characterised by fever and widespread rash. Maternal antibody usually gives protection for the first 6–12 months of life. Comprehensive immunisation programmes have dramatically reduced the number of paediatric infections but incomplete uptake results in infections in later life.

Measles

The WHO has set the objective of eradicating measles globally using the live attenuated vaccine. However, vaccination of more than 95% of the population is required to prevent outbreaks. Natural illness produces life-long immunity.

Clinical features

Infection is by respiratory droplets with an incubation period of 6–19 days. A prodromal illness occurs, 1–3 days before the rash, with upper respiratory symptoms, conjunctivitis and the presence of the pathognomonic Koplik’s spots: small white spots surrounded by erythema on the buccal mucosa (Fig. 11.8A). As natural antibody develops, the maculopapular rash appears, spreading from the face to the extremities (Fig. 11.8B). Generalised lymphadenopathy and diarrhoea are common. Complications are more common in older children and adults, and include otitis media, bacterial pneumonia, transient hepatitis, pancreatitis and clinical encephalitis (approximately 0.1% of cases). A rare late complication is subacute sclerosing panencephalitis (SSPE), which occurs up to 7 years after infection. Diagnosis is clinical (although this has become unreliable in areas where measles is no longer common) and by detection of antibody (serum immunoglobulin M [IgM], seroconversion or salivary IgM).

Measles is a serious disease in the malnourished, vitamin-deficient or immunocompromised, in whom the typical rash may be missing and persistent infection with a giant cell pneumonitis or encephalitis may occur. In tuberculosis infection, measles suppresses cell-mediated immunity and may exacerbate disease; for this reason, measles vaccination should be deferred until after commencing antituberculous treatment. Measles does not cause congenital malformation but may be more severe in pregnant women.

Mortality clusters at the extremes of age, averaging 1 : 1000 in developed countries and up to 1 : 4 in developing countries. Death usually results from a bacterial superinfection, occurring as a complication of measles: most often pneumonia, diarrhoeal disease or noma/cancrum oris, a gangrenous stomatitis. Death may also result from complications of measles encephalitis.

Management and prevention

Normal immunoglobulin attenuates the disease in the immunocompromised (regardless of vaccination status) and in non-immune pregnant women, but must be given within 6 days of exposure. Vaccination can be used in outbreaks and vitamin A may improve the outcome in uncomplicated disease. Antibiotic therapy is reserved for bacterial complications. All children aged 12–15 months should receive measles vaccination (as combined measles, mumps and rubella [MMR], a live attenuated vaccine), and a further MMR dose at age 4 years.

Rubella (German measles)

Rubella causes exanthem in the non-immunised.

Clinical features

Rubella is spread by respiratory droplet, with infectivity from up to 10 days before to 2 weeks after the onset of the rash. The incubation period is 15–20 days. In childhood, most cases are subclinical, although clinical features may include fever, maculopapular rash spreading from the face, and lymphadenopathy. Complications are rare but include thrombocytopenia and hepatitis. Encephalitis and haemorrhage are occasionally reported. In adults, arthritis involving hands or knees is relatively common, especially in women.

If transplacental infection takes place in the first trimester or later, persistence of the virus is likely and severe congenital disease may result (Box 11.27). Even if normal at birth, the infant has an increased incidence of other diseases developing later, e.g. diabetes mellitus.

Diagnosis

Laboratory confirmation of rubella is required if there has been contact with a pregnant woman. This is achieved either by detection of rubella IgM in serum or by IgG seroconversion. In the exposed pregnant woman, absence of rubella-specific IgG confirms the potential for congenital infection.

Prevention

All children should be immunised with MMR vaccine. Congenital rubella syndrome may be controlled by testing women of child-bearing age for rubella antibodies and offering vaccination if seronegative. Antenatal rubella screening was offered to pregnant mothers in the UK for many years for this reason. However, this...
Persistent viraemia in immunocompromised hosts may require immunoglobulin therapy to clear the virus.

Pregnant women should avoid contact with cases of parvovirus B19 infection, and if they are exposed, serology should be performed to establish whether they are non-immune.

Passive prophylaxis with normal immunoglobulin has been suggested for non-immune pregnant women exposed to infection but there are limited data to support this recommendation. The pregnancy should be closely monitored by ultrasound scanning, so that hydrops fetalis can be treated by fetal transfusion.

**Parvovirus B19**

Parvovirus B19 causes exanthem and other clinical syndromes. Some 50% of children and 60–90% of adults are seropositive. Most infections are spread by the respiratory route, although spread via contaminated blood is also possible. The virus has particular tropism for red cell precursors.

### Clinical features

Many infections are subclinical. Clinical manifestations result after an incubation period of 14–21 days (Box 11.28). The classic exanthem (erythema infectiosum) is preceded by a prodromal fever and coryzal symptoms. A ‘slapped cheek’ rash is characteristic but the rash is very variable (Fig. 11.9). In adults, polyarthropathy is common. Infected individuals have a transient block in erythropoiesis for a few days, which is of no clinical consequence, except in individuals with increased red cell turnover due to haemoglobinopathy or haemolytic anaemia. These individuals develop an acute anaemia that may be severe (transient aplastic crisis; p. 968). Erythropoiesis usually recovers spontaneously after 10–14 days. Immunocompromised individuals, including those with congenital immunodeficiency or AIDS, can develop a more sustained block in erythropoiesis in response to the chronic viraemia that results from their inability to clear the infection. Infection during the first two trimesters of pregnancy can result in intrauterine infection and impact on fetal bone marrow; it causes 10–15% of non-immune (non-Rhesus-related) hydrops fetalis, a rare complication of pregnancy.

### Diagnosis

IgM to parvovirus B19 suggests recent infection but may persist for months and false positives occur. Seroconversion to IgG positivity confirms infection but in isolation a positive IgG is of little diagnostic utility. Detection of parvovirus B19 DNA in blood is particularly useful in immunocompromised patients. Giant pronormoblasts or haemophagocytosis may be demonstrable in the bone marrow.

### Management

Infection is usually self-limiting. Symptomatic relief for arthritic symptoms may be required. Severe anaemia requires transfusion.
Human herpesvirus 6 and 7

Human herpesvirus 6 (HHV-6) is a lymphotropic virus that causes a childhood viral exanthem (exanthem subitum), rare cases of an infectious mononucleosis-like syndrome and infection in the immunocompromised host. Infection is almost universal, with approximately 95% of children acquiring this virus by 2 years of age. Transmission is via saliva.

HHV-7 is very closely related to HHV-6 and is believed to be responsible for a proportion of cases of exanthem subitum. Like HHV-6, HHV-7 causes an almost universal infection in childhood, with subsequent latent infection and occasional infection in the immunocompromised host.

Clinical features

Exanthem subitum is also known as roseola infantum or sixth disease (Box 11.29). A high fever is followed by a maculopapular rash as the fever resolves. Fever and/or febrile convulsions may also occur without a rash. Rarely, older children or adults may develop an infectious mononucleosis-like illness, hepatitis or rash. In the immunocompromised, infection is rare but can cause fever, rash, hepatitis, pneumonitis, cytopenia or encephalitis.

Diagnosis and management

Exanthem subitum is usually a clinical diagnosis but can be confirmed by antibody and/or DNA detection. The disease is self-limiting. Treatment with ganciclovir or foscarnet is used in immunocompromised hosts infected with HHV-6.

Chickenpox (varicella)

Varicella zoster virus (VZV) is a dermotropic and neurotropic virus that produces primary infection, usually in childhood, which may reactivate in later life. VZV is spread by aerosol and direct contact. It is highly infectious to non-immune individuals. Disease in children is usually well tolerated. Manifestations are more severe in adults, pregnant women and the immunocompromised.

Clinical features

The incubation period is 11–20 days, after which a vesicular eruption begins (Fig. 11.10), often on mucosal surfaces first, followed by rapid dissemination in a centripetal distribution (most dense on trunk and sparse on limbs). New lesions occur every 2–4 days and each crop is associated with fever. The rash progresses from small pink macules to vesicles and pustules within 24 hours. Infectivity lasts from up to 4 days (but usually 48 hours) before the lesions appear until the last vesicles crust over. Due to intense itching, secondary bacterial infection from scratching is the most common complication of primary chickenpox. Self-limiting cerebellar ataxia and encephalitis are rare complications.

Adults, pregnant women and the immunocompromised are at increased risk of visceral involvement, which presents as pneumonitis, hepatitis or encephalitis. Pneumonitis can be fatal and is more likely to occur in smokers. Maternal infection in
early pregnancy carries a 3% risk of neonatal damage with developmental abnormalities of eyes, CNS and limbs. Chickenpox within 5 days of delivery leads to severe neonatal varicella with visceral involvement and haemorrhage.

**Diagnosis**

Diagnosis is primarily clinical, by recognition of the rash. If necessary, this can be confirmed by detection of antigen (direct immunofluorescence) or DNA (PCR) of aspirated vesicular fluid. Serology is used to identify seronegative individuals at risk of infection.

**Management and prevention**

The benefits of antivirals for uncomplicated primary VZV infection in children are marginal, shortening the duration of rash by only 1 day, and treatment is not normally required. Antivirals are, however, used for uncomplicated chickenpox in adults when the patient presents within 24–48 hours of onset of vesicles, in all patients with complications, and in those who are immunocompromised, including pregnant women, regardless of duration of vesicles (Box 11.30). More severe disease, particularly in immunocompromised hosts, requires initial parenteral therapy. Immunocompromised patients may have prolonged viral shedding and may require prolonged treatment until all lesions crust over.

Human VZ immunoglobulin (VZIG) is used to attenuate infection in people who have had significant contact with VZV, are susceptible to infection (i.e. have no history of chickenpox or shingles and are seronegative for VZV IgG) and are at risk of severe disease (e.g. immunocompromised or pregnant) (Box 11.31). Ideally, VZIG should be given within 7 days of exposure, but it may attenuate disease even if given up to 10 days afterwards. Susceptible contacts who develop severe chickenpox after receiving VZIG should be treated with aciclovir.

A live, attenuated VZV vaccine is available and in routine use in the USA and other countries, but in the UK its use has been restricted to non-immune health-care workers and household contacts of immunocompromised individuals. Children receive one dose after 1 year of age and a second dose at 4–6 years of age; seronegative adults receive two doses at least 1 month apart. The vaccine may also be used prior to planned iatrogenic immunosuppression, e.g. before transplant and for the elderly aged over 70 to prevent shingles.

### Shingles (herpes zoster)

After initial infection, VZV persists in latent form in the dorsal root ganglion of sensory nerves and can reactivate in later life.

**Clinical features**

Burning discomfort occurs in the affected dermatome following reactivation and discrete vesicles appear 3–4 days later. This is associated with a brief viraemia, which can produce distant satellite ‘chickenpox’ lesions. Occasionally, paraesthesia occurs without rash (‘zoster sine herpete’). Severe disease, a prolonged duration of rash, multiple dermatomal involvement or recurrence suggests underlying immune deficiency, including HIV. Chickenpox may be contracted from a case of shingles but not vice versa.

Although thoracic dermatomes are most commonly involved (Fig. 11.10B), the ophthalmic division of the trigeminal nerve is also frequently affected; vesicles may appear on the cornea and lead to ulceration. This condition can lead to blindness and urgent ophthalmology review is required. Geniculate ganglion involvement causes the Ramsay Hunt syndrome of facial palsy, ipsilateral loss of taste and buccal ulceration, plus a rash in the external auditory canal. This may be mistaken for Bell’s palsy (p. 1082). Bowel and bladder dysfunction occur with sacral nerve root involvement. The virus occasionally causes cranial nerve palsy, myelitis or encephalitis. Granulomatous cerebral angiitis is a cerebrovascular complication that leads to a stroke-like syndrome in association with shingles, especially in an ophthalmic distribution.

Post-herpetic neuralgia causes troublesome persistence of pain for 1–6 months or longer, following healing of the rash. It is more common with advanced age.

(CNS = central nervous system; HSV = herpes simplex virus; VZV = varicella zoster virus)
Management

Early therapy with aciclovir or related agents has been shown to reduce both early- and late-onset pain, especially in patients over 65 years. Post-herpetic neuralgia requires aggressive analgesia, along with agents such as amitriptyline 25–100 mg daily, gabapentin (commencing at 300 mg daily and building slowly to 300 mg twice daily or more) or pregabalin (commencing at 75 mg twice daily and building up to 100 mg or 200 mg 3 times daily if tolerated). Capsaicin cream (0.075%) may be helpful. Although controversial, glucocorticoids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR vaccine.

Enteroviral exanthems

Coxsackie or echovirus infections can lead to a maculopapular eruption or roseola-like rash that occurs after fever falls. Enteroviral infections are discussed further under viral infections of the skin (see below).

Systemic viral infections without exanthem

Other systemic viral infections present with features other than a rash suggestive of exanthem. Rashes may occur in these conditions but differ from those seen in exanthems or are not the primary presenting feature.

Mumps

Mumps is a systemic viral infection characterised by swelling of the parotid glands. Infection is endemic worldwide and peaks at 5–9 years of age. Vaccination has reduced the incidence in children but incomplete coverage and waning immunity with time have led to outbreaks in young adults. Infection is spread by respiratory droplets.

Clinical features

The median incubation period is 19 days, with a range of 15–24 days. Classical tender parotid enlargement, which is bilateral in 75%, follows a prodrome of pyrexia and headache (Fig. 11.11). Meningitis complicates up to 10% of cases. The CSF reveals a lymphocytic pleocytosis or, less commonly, neutrophils. Rare complications include encephalitis, transient hearing loss, labyrinthitis, electrocardiographic abnormalities, pancreatitis and arthritis.

Approximately 25% of post-pubertal males with mumps develop epididymo-orchitis but, although testicular atrophy occurs, sterility is unlikely. Oophoritis is less common. Abortion may occur if infection takes place in the first trimester of pregnancy. Complications may occur in the absence of parotitis.

Diagnosis

The diagnosis is usually clinical. In atypical presentations without parotitis, serology for mumps-specific IgM or IgG seroconversion (fourfold rise in IgG convalescent titre) confirms the diagnosis. Virus can also be cultured from urine in the first week of infection or detected by PCR in urine, saliva or CSF.

Management and prevention

Treatment is with analgesia. There is no evidence that glucocorticoids are of value for orchitis. Mumps vaccine is one of the components of the combined MMR vaccine.

Influenza

Influenza is an acute systemic viral infection that primarily affects the respiratory tract and carries a significant mortality. It is caused by influenza A virus or, in milder form, influenza B virus. Infection is seasonal, and variation in the haemagglutinin (H) and neuraminidase (N) glycoproteins on the surface of the virus leads to disease of variable intensity each year. Minor changes in haemagglutinin are known as ‘genetic drift’, whereas a switch in the haemagglutinin or neuraminidase antigen is termed ‘genetic shift’. Nomenclature of influenza strains is based on these glycoproteins, e.g. H1N1, H3N2 etc. Genetic shift results in the circulation of a new influenza strain within a community to
which few people are immune, potentially initiating an influenza epidemic or pandemic in which there is a high attack rate and there may be increased disease severity.

**Clinical features**

After an incubation period of 1–3 days, uncomplicated disease leads to fever, malaise and cough. Viral pneumonia may occur, although pulmonary complications are most often due to superinfection with *Strep, pneumonieae, Staph, aureus* or other bacteria. Rare extrapulmonary manifestations include myositis, myocarditis, pericarditis and neurological complications (Reye’s syndrome in children, encephalitis or transverse myelitis). Mortality is greatest in the elderly, those with medical comorbidities and pregnant women. Polymorphisms in the gene encoding an antiviral protein, interferon-induced transmembrane protein 3 (IFITM3), are associated with more severe influenza.

**Diagnosis**

Acute infection is diagnosed by viral antigen or RNA detection in a nasopharyngeal sample. The disease may also be diagnosed retrospectively by serology.

**Management and prevention**

Management involves early microbiological identification of cases and good infection control, with an emphasis on hand hygiene and preventing dissemination of infection by coughing and sneezing. Administration of neuraminidase inhibitor, oral oseltamivir (75 mg twice daily) or inhaled zanamivir (10 mg twice daily) for 5 days, can reduce the severity of symptoms if started within 48 hours of symptom onset (or possibly later in immunocompromised individuals). These agents have superseded routine use of amantadine and rimantadine. Antiviral drugs can also be used as prophylaxis in high-risk individuals during the ‘flu’ season. Resistance can emerge to all of these agents and so updated local advice should be followed with regard to the sensitivity to antivirals of the circulating strain.

Prevention relies on seasonal vaccination of the elderly, children 2–7 years of age and individuals with chronic medical illnesses that place them at increased risk of the complications of influenza, such as chronic cardiopulmonary diseases or immune compromise, as well as their health-care workers. The vaccine composition changes each year to cover the ‘predicted’ seasonal strains but vaccination may fail when a new pandemic strain emerges.

**Avian influenza**

Avian influenza is caused by transmission of avian influenza A viruses to humans. Avian viruses, such as H5N1, possess alternative haemagglutinin antigens to seasonal influenza strains. Most cases have had contact with sick poultry, predominantly in South-east Asia, and person-to-person spread has been limited to date. Infections with H5N1 viruses have been severe, with enteric features and respiratory failure. Treatment depends on the resistance pattern but often involves oseltamivir. Vaccination against seasonal ‘flu’ does not adequately protect against avian influenza. There is a concern that adaptation of an avian strain to allow effective person-to-person transmission is likely to lead to a global pandemic of life-threatening influenza.

**Swine influenza**

Re-assortment of swine, avian and human influenza strains can occur in pigs and lead to outbreaks of swine ‘flu’ in humans, as occurred in 2009, when an outbreak of H1N1pdm2009 influenza spread around the world from Mexico. Cases were still occurring in the Indian subcontinent in 2014–16. Symptoms included more gastrointestinal symptoms than with seasonal influenza, respiratory failure and seizures or encephalitis. Severe disease was a feature of infants, adults less than 50 years, those with chronic lung or neurological disease, obese patients and pregnant women, but with time the clinical features have become indistinguishable from those of seasonal influenza.

### Infectious mononucleosis and Epstein–Barr virus

Infectious mononucleosis (IM) is a clinical syndrome characterised by pharyngitis, cervical lymphadenopathy, fever and lymphocytosis (known colloquially as glandular fever). It is most often caused by Epstein–Barr virus (EBV) but other infections can produce a similar clinical syndrome (Box 11.32).

EBV is a gamma herpesvirus. In developing countries, subclinical infection in childhood is virtually universal. In developed countries, primary infection may be delayed until adolescence or early adult life. Under these circumstances, about 50% of infections result in typical IM. The virus is usually acquired from asymptomatic excreters via saliva, either by droplet infection or environmental contamination in childhood, or by kissing among adolescents and adults. EBV is not highly contagious and isolation of cases is unnecessary.

**Clinical features**

EBV infection has a prolonged but undetermined incubation period, followed in some cases by a prodrome of fever, headache and malaise. This is followed by IM with severe pharyngitis, which may include tonsillar exudates and non-tender anterior and posterior cervical lymphadenopathy. Palatal petechiae, splenomegaly, inguinal or axillary lymphadenopathy, and macular, petechial or erythema multiforme rashes may occur. In most cases, fever resolves over 2 weeks, and fatigue and other abnormalities settle over a further few weeks. Complications are listed in Box 11.33. Death is rare but can occur due to respiratory obstruction, haemorrhage from splenic rupture, thrombocytopenia or encephalitis.

The diagnosis of EBV infection outside the usual age in adolescence and young adulthood is more challenging. In children under 10 years the illness is mild and short-lived, but in adults over 30 years of age it can be severe and prolonged. In both groups, pharyngeal symptoms are often absent. EBV may present with jaundice, as a PUO or with a complication.

**Long-term complications of EBV infection**

Lymphoma complicates EBV infection in immunocompromised hosts, and some forms of Hodgkin lymphoma are EBV-associated (p. 961). The endemic form of Burkitt’s lymphoma complicates EBV infection in areas of sub-Saharan Africa where *falciparum* malaria is endemic. Nasopharyngeal carcinoma is a geographically restricted tumour seen in China and Alaska that is associated with EBV infection. X-linked lymphoproliferative (Duncan’s) syndrome is a familial lymphoproliferative disorder that follows primary EBV infection in boys without any other history of immunodeficiency;
of test serum to agglutinate sheep and horse red blood cells, respectively.). Sometimes antibody production is delayed, so an initially negative test should be repeated. However, many children and 10% of adolescents with IM do not produce heterophile antibody at any stage.

Specific EBV serology confirms the diagnosis. Acute infection is characterised by IgM antibodies against the viral capsid, antibodies to EBV early antigen and the initial absence of antibodies to EBV nuclear antigen (anti-EBNA). Seroconversion of anti-EBNA at approximately 1 month after the initial illness may confirm the diagnosis in retrospect. CNS infections may be diagnosed by detection of viral DNA in CSF.

Management

Treatment is largely symptomatic. If a throat culture yields a β-haemolytic streptococcus, penicillin should be given. Administration of ampicillin or amoxicillin in this condition commonly causes an itchy macular rash and should be avoided (Fig. 11.12B). When pharyngeal oedema is severe, a short course of glucocorticoids, e.g. prednisolone 30 mg daily for 5 days, may help. Current antiviral drugs are not active against EBV. Return to work or school is governed by physical fitness rather than laboratory tests; contact sports should be avoided until splenomegaly has resolved because of the danger of splenic rupture. Unfortunately, about 10% of patients with IM suffer a chronic relapsing syndrome.

Cytomegalovirus

Cytomegalovirus (CMV), like EBV, circulates readily among children. A second period of virus acquisition occurs among teenagers and young adults, peaking between the ages of 25 and 35 years, rather later than with EBV infection. CMV infection is persistent, and is characterised by subclinical cycles of active virus replication and by persistent low-level virus shedding. Most post-childhood infections are therefore acquired from asymptomatic excretors who shed virus in saliva, urine, semen and genital secretions. Sexual transmission and oral spread are common among adults but infection may also be acquired by women caring for children with asymptomatic infections.

Clinical features

Most post-childhood CMV infections are subclinical, although some young adults develop an IM-like syndrome and some have a prolonged influenza-like illness lasting 2 weeks or more. Physical signs resemble those of IM but in CMV infections hepatomegaly is
more common, while lymphadenopathy, splenomegaly, pharyngitis and tonsillitis occur less often. Jaundice is uncommon and usually mild. Complications include myocardiitis, rhabdomyolysis, hepatic necrosis, disseminated intravascular coagulation (DIC; p. 978). Previously, dengue was seen in small children and DHF/DSS in children 2–15 years old, but these conditions are now being seen in children less than 2 years old, and most frequently in those 16–45 years of age or older, in whom severe organ dysfunction is more common. Other epidemiological changes include the spread of dengue into rural communities and greater case fatality in women.

**Investigations**

Atypical lymphocytosis is not as prominent as in EBV infection and heterophile antibody tests are usually negative. LFTs are often abnormal, with an alkaline phosphatase level raised out of proportion to transaminases. Serological diagnosis depends on the detection of CMV-specific IgM antibody plus a fourfold rise or seroconversion of IgG. In the immunocompromised, antibody detection is unreliable and detection of CMV in an involved organ by PCR, antigen detection, culture or histopathology establishes the diagnosis. Detection of CMV in the blood may be useful in transplant populations but not in HIV-positive individuals, since in HIV infection CMV reactivates at regular intervals, but these episodes do not correlate well with episodes of clinical disease. Detection of CMV in urine is not helpful in diagnosing infection, except in neonates, since CMV is intermittently shed in the urine throughout life following infection.

**Management**

Only symptomatic treatment is required in the immunocompetent patient. Immunocompromised individuals are treated with ganciclovir 5 mg/kg IV twice daily or with oral valganciclovir 900 mg twice daily for at least 14 days. Foscarnet or cidofovir is also used in CMV treatment of immunocompromised patients who are resistant to or intolerant of ganciclovir-based therapy. They can be given intravitreally if required.

**Dengue**

Dengue is a febrile illness caused by a flavivirus transmitted by mosquito. It is endemic in Asia, the Pacific, Africa and the Americas (Fig. 11.13). Approximately 400 million infections and 100 million clinically apparent infections occur annually, and dengue is the most rapidly spreading mosquito-borne viral illness. The principal vector is the mosquito *Aedes aegypti*, which breeds in standing water; collections of water in containers, water-based air coolers and tyre dumps are a good environment for the vector in large cities. *Aedes albopictus* is a vector in some South-east Asian countries. There are four serotypes of dengue virus, all producing a similar clinical syndrome; type-specific immunity is life-long but immunity against the other serotypes lasts only a few months. Dengue haemorrhagic fever (DHF) and dengue shock syndrome (DSS) occur in individuals who are immune to one dengue virus serotype and are then infected with another. Prior immunity results in increased uptake of virus by cells expressing the antibody Fc receptor and increased T-cell activation with resultant cytokine release, causing capillary leak and disseminated intravascular coagulation (DIC; p. 979). Previously, dengue was seen in small children and DHF/DSS in children 2–15 years old, but these conditions are now being seen in children less than 2 years old, and most frequently in those 16–45 years of age or older, in whom severe organ dysfunction is more common. Other epidemiological changes include the spread of dengue into rural communities and greater case fatality in women.

**Clinical features**

Many cases of dengue infection are asymptomatic in children. Clinical disease presents with undifferentiated fever termed dengue-like illness. When dengue infection occurs with characteristic symptoms or signs it is termed ‘dengue’ (Box 11.34). A rash frequently follows the initial febrile phase as the fever settles. Laboratory features include leucopenia, neutropenia,

**Convalescence**

- Slow and may be associated with prolonged fatigue syndrome, arthralgia or depression

**Complications**

- Dengue haemorrhagic fever and disseminated intravascular coagulation
- Dengue shock syndrome
- Severe organ involvement
- Vertical transmission if infection within 5 weeks of delivery

**Prodrome**

- 2 days of malaise and headache

**Acute onset**

- Fever, backache, arthralgias, headache, generalised pains (‘break-bone fever’), pain on eye movement, lacrimation, scleral injection, anorexia, nausea, vomiting, pharyngitis, upper respiratory tract symptoms, relative bradycardia, prostration, depression, hyperaesthesia, dygeusia, lymphadenopathy

**Fever**

- Continuous or ‘saddle-back’, with break on 4th or 5th day and then recrudescence; usually lasts 7–8 days

**Rash**

- Initial flushing faint macular rash in first 1–2 days. Maculopapular, scarlet morbilliform blanching rash from days 3–5 on trunk, spreading centrifugally and sparing palms and soles; onset often with fever defervescence. May desquamate on resolution or give rise to petechiae on extensor surfaces
thrombocytopenia and elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST). Many symptomatic infections run an uncomplicated course but complications or a protracted convalescence may ensue. Warning signs justify intense medical management and monitoring for progression to severe dengue. Atypical clinical features of dengue are increasingly common, especially in infants or older patients (Box 11.35). These, along with DHF or DSS, are recognised as features of severe dengue in the 2015 case definition.

The period 3–7 days after onset of fever is termed the ‘critical’ phase, during which signs of DHF or DSS may develop. In mild forms, petechiae occur in the arm when a blood pressure cuff is inflated to a point between systolic and diastolic blood pressure and left for 5 minutes (the positive ‘tourniquet test’) – a non-specific test of capillary fragility and thrombocytopenia. As the extent of capillary leak increases, DSS develops, with non-specific test of capillary fragility and thrombocytopenia.

Mild forms, petechiae occur in the arm when a blood pressure cuff is inflated to a point between systolic and diastolic blood pressure and left for 5 minutes (the positive ‘tourniquet test’) – a non-specific test of capillary fragility and thrombocytopenia. As the extent of capillary leak increases, DSS develops, with a raised haematocrit, tachycardia and hypotension, pleural effusions and ascites. This may progress to metabolic acidosis and multi-organ failure, including acute respiratory distress syndrome (ARDS; p. 198). Minor (petechiae, ecchymoses, epistaxis) or major (gastrointestinal or vaginal) haemorrhage, a feature of DHF, may occur. Cerebrovascular bleeding may be a complication of severe dengue.

**Diagnosis**

In endemic areas, mild dengue must be distinguished from other viral infections. The diagnosis can be confirmed by seroconversion of IgM or a fourfold rise in IgG antibody titres. Serological tests may detect cross-reacting antibodies from infection or vaccination against other flaviviruses, including yellow fever virus, Japanese encephalitis virus and West Nile virus. Isolation of dengue virus or detection of dengue virus RNA by PCR (p. 106) in blood or CSF is available in specialist laboratories. Commercial enzyme-linked immunosorbent assay (ELISA) kits to detect the NS1 viral antigen, although less sensitive than PCR, are available in many endemic areas.

**Management and prevention**

Treatment is supportive, emphasising fluid replacement and appropriate management of shock and organ dysfunction, which is a major determinant of morbidity and mortality. With intensive care support, mortality rates are 1% or less. Aspirin should be avoided due to bleeding risk. Glucocorticoids have not been shown to help. No existing antivirals are effective.

Breeding places of Aedes mosquitoes should be abolished and the adults destroyed by insecticides. A recently licensed vaccine is available.

**Yellow fever**

Yellow fever is a haemorrhagic fever of the tropics, caused by a flavivirus. It is a zoonosis of monkeys in West and Central African, and South and Central American tropical rainforests, where it may cause devastating epidemics (Fig. 11.13). Transmission is by tree-top mosquitoes, Aedes africanus (Africa) and Haemagogus spp. (America). The infection is introduced to humans either by infected mosquitoes when trees are felled, or by monkeys raiding human settlements. In towns, yellow fever may be transmitted between humans by Aedes aegypti, which breeds efficiently in small collections of water. The distribution of this mosquito is far wider than that of yellow fever, and more widespread infection is a continued threat.

Yellow fever causes approximately 200 000 infections each year, mainly in sub-Saharan Africa, and the number is increasing. Overall mortality is around 15%, although this varies widely. Humans are infectious during the viraemic phase, which starts 3–6 days after the bite of the infected mosquito and lasts for 4–5 days.

**Clinical features**

After an incubation period of 3–6 days, yellow fever is often a mild febrile illness lasting less than 1 week, with headache, myalgia, conjunctival erythema and bradycardia. This is followed by fever resolution (defervescence) but, in some cases, fever recurs after a few hours to days. In more severe disease, fever recrudescence is associated with lower back pain, abdominal pain and somnolence, prominent nausea and vomiting, bradycardia and jaundice. Liver damage and DIC lead to bleeding with petechiae, mucosal haemorrhages and gastrointestinal bleeding. Shock, hepatic failure, renal failure, seizures and coma may ensue.
Diagnosis

The differential diagnosis includes malaria, typhoid, viral hepatitis, leptospirosis, haemorrhagic fevers and aflatoxin poisoning. Diagnosis of yellow fever can be confirmed by detection of virus in the blood in the first 3–4 days of illness (e.g. by culture or reverse transcription polymerase chain reaction (RT-PCR)), the presence of IgM or a fourfold rise in IgG antibody titre. Leucopenia is characteristic. Liver biopsy should be avoided in life due to the risk of fatal bleeding. Postmortem features, such as acute mid-zonal necrosis and Councilman bodies with minimal inflammation in the liver, are suggestive but not specific. Immunohistochemistry for viral antigens improves specificity.

Management and prevention

Treatment is supportive, with meticulous attention to fluid and electrolyte balance, urine output and blood pressure. Blood transfusions, plasma expanders and peritoneal dialysis may be necessary. Patients should be isolated, as their blood and body products may contain virus particles.

A single vaccination with a live attenuated vaccine gives full protection for at least 10 years and many travellers do not require a booster unless specified by individual countries’ travel requirements. Potential side-effects include hypersensitivity, encephalitis and systemic features of yellow fever (viscerotropic disease) caused by the attenuated virus. Vaccination is not recommended in people who are significantly immunosuppressed. The risk of vaccine side-effects must be balanced against the risk of infection for less immunocompromised hosts, pregnant women and older patients. An internationally recognised certificate of vaccination is sometimes necessary when crossing borders.

Viral haemorrhagic fevers

Viral haemorrhagic fevers (VHFs) are zoonoses caused by several different viruses (Box 11.36). They are geographically restricted and previously occurred in rural settings or in health-care facilities. The largest outbreak of VHF to date started in 2014, with Ebola

1 All potentially have circulatory failure. 2 Mortality of uncomplicated and haemorrhagic dengue fever, respectively. (ARDS = acute respiratory distress syndrome)
circulating in Guinea, Liberia and Sierra Leone. The outbreak resulted in over 28,000 cases by 2016. Serological surveys have shown that Lassa fever is widespread in West Africa and may lead to up to 500,000 infections annually. Mortality overall may be low, as 80% of cases are asymptomatic, but in hospitalised cases mortality averages 15%. Ebola outbreaks have occurred at a rate of approximately one per year in Africa, involving up to a few hundred cases prior to the 2014 outbreak. Marburg has been documented less frequently, with outbreaks in the Democratic Republic of Congo and Uganda, but the largest outbreak to date involved 163 cases in Angola in 2005. Mortality rates of Ebola and Marburg are high.

VHF s have extended into Europe, with an outbreak of Congo–Crimean haemorrhagic fever (CCHF) in Turkey in 2006, and cases of haemorrhagic fever with renal syndrome in the Balkans and Russia. An outbreak of CCHF in 2011 in Gujarat, India, involved several health-care workers and emphasised the importance of maintaining a high index of suspicion for VHF and implementing appropriate infection control measures at the first opportunity. Kyaasunr forest disease is a tick-borne VHF currently confined to a small focus in Karnataka, India; there are about 500 cases annually. Monkeys are the principal hosts but, with forest felling, there are fears that this disease will increase.

New outbreaks and new agents are identified sporadically. Details on recent disease outbreaks can be found at the WHO website (see ‘Further information’).

**Clinical features**

VHF s present with non-specific fever, malaise, body pains, sore throat and headache. On examination, conjunctivitis, throat injection, an erythematic or petechial rash, haemorrhage, lymphadenopathy and bradycardia may be noted. The viruses cause endothelial dysfunction with the development of capillary leak. Bleeding is due to endothelial damage and platelet dysfunction. Hypovolaemic shock and ARDS may develop.

Haemorrhage is a late feature of most VHFs and most patients present with earlier features. In Lassa fever, joint and abdominal pain is prominent. A macular blanching rash may be present but bleeding is unusual, occurring in only 20% of hospitalised patients. Encéphalopathy may develop and deafness affects 30% of survivors. In CCHF, bleeding, manifest by haematemesis or bleeding per rectum, may be an early feature, accompanied by derangement of LFTs.

The clue to the viral aetiology comes from the travel and exposure history. Travel to an outbreak area, activity in a rural environment and contact with sick individuals or animals within 21 days all increase the risk of VHF. Enquiry should be made about insect bites, hospital visits and attendance at ritual funerals (Ebola virus infection). In Lassa fever, retrosternal pain, pharyngitis and proteinuria have a positive predictive value of 80% in West Africa.

**Investigations and management**

Non-specific findings include leucopenia, thrombocytopenia and proteinuria. In Lassa fever, an AST of > 150 U/L is associated with a 50% mortality. It is important to exclude other causes of fever, especially malaria, typhoid and respiratory tract infections. Most patients suspected of having a VHF in the UK turn out to have malaria.

A febrile patient from an endemic area within the 21-day incubation period, who has specific epidemiological risk factors (see Fig. 11.6) or signs of organ failure or haemorrhage, should be treated as being at high risk of VHF; appropriate infection control measures must be implemented and the patient transferred to a centre with biosecurity level (BSL) 4 facilities if testing positive. Individuals with a history of travel within 21 days and fever, but without the relevant epidemiological features or signs of VHF, are classified as medium-risk and should have an initial blood sample tested to exclude malaria. If this is negative, relevant specimens (blood, throat swab, urine and pleural fluid, if available) are collected and sent to an appropriate reference laboratory for nucleic acid detection (PCR), virus isolation and serology. If patients are still felt to be at significant risk of VHF or if infection is confirmed, they should be transferred to a specialised high-security infectious disease unit. All further laboratory tests should be performed at BSL 4. Transport requires an ambulance with BSL 3 facilities.

In addition to general supportive measures, ribavirin is given intravenously (100 mg/kg, then 25 mg/kg daily for 3 days and 12.5 mg/kg daily for 4 days) when Lassa fever or South American haemorrhagic fevers are suspected.

**Prevention**

Ribavirin has been used as prophylaxis in close contacts in Lassa fever but there are no formal trials of its efficacy.

**Ebola virus disease (EVD)**

Ebola virus disease (EVD) is thought to spread to human populations from fruit bats, sometimes indirectly via contact with infected primates or other animals. Person-to-person spread, via contact with blood, secretions or body parts, establishes EVD in populations. Family members, health-care workers and people performing traditional burials are at particular risk. The 2014 outbreak involved the Zaire strain of Ebola virus.

**Clinical features**

The incubation period is 2–21 days but typically 8–10 days. Fever and non-specific signs are accompanied by abdominal pain, diarrhoea, vomiting and hiccups. A maculopapular rash occurs after 5–7 days in some. Although bleeding from the gums or venepuncture sites or in the stool occurs, haemorrhage may be less prominent than in other VHFs and is often a terminal event, as observed in the 2014 epidemic. In contrast, fluid losses from diarrhoea are more marked and reach 10 L a day. Complications include meningoencephalitis, uveitis and miscarriages in pregnant women.

**Investigations**

Lymphopenia occurs, followed by neutrophilia, atypical lymphocytes, thrombocytopenia and coagulation abnormalities. Elevations of AST/ALT, features of acute kidney injury, electrolyte disturbances and proteinuria are also observed. The virus is detected by a PCR in blood or body fluids, but may need retesting if the duration of symptoms is less than 3 days. Serology provides a retrospective diagnosis.

**Management**

Treatment is supportive and aimed at fluid replacement. Bacterial super-infections should be promptly treated. A cocktail of monoclonal antibodies against Ebola virus, ZMapp, has been used in a few cases, but efficacy requires further studies. Mortality is approximately 40%. Survivors recover from the second week of illness but experience late sequelae, including arthritis (76%), uveitis (60%) and deafness (24%), while skin sloughing is common. Relapse with meningitis is reported months after recovery.
Prevention

Ebola virus may be detected in the semen months after recovery. Male survivors are therefore encouraged to practice safe sex for 12 months after symptom onset or until semen tests negative on two occasions, but recommendations are evolving. Public health measures are essential for outbreak control and involve contact surveillance and monitoring through the incubation period, separating healthy from sick individuals, practicing safe burial methods and ensuring appropriate infection control measures to protect health-care and laboratory workers, including provision of personal protective equipment such as gloves, gowns and full-face protection (face shield or masks combined with goggles). An Ebola glycoprotein vaccine, rVZV-ZEBOV, was shown to be effective in 2016 after a trial in West Africa.

**Zika virus**

Zika virus is a flavivirus spread from primate hosts by *Aedes aegypti* and *Aedes albopictus*, which bite during the day. Described in Africa and Asia since 2015, it has been epidemic in the Caribbean and Central and South America, where a mosquito–man–mosquito transmission cycle is established. It also can be transmitted in semen.

**Clinical features**

The incubation period is 3–12 days. Infection is asymptomatic or mild, resembling dengue with fever, arthralgia, conjunctivitis and maculopapular rash. Complications include increased reports of Guillain–Barré syndrome. The major concern has been a marked increase in microcephaly in pregnant women infected with Zika virus, as well as increased rates of cerebral calcification, deafness, visual problems such as chorioretinal scarring, joint contractures (arthrogryposis), hydrops fetalis and growth retardation. Zika virus appears to infect neural progenitor cells.

**Investigations**

Routine blood tests are usually normal but may show leucopenia, thrombocytopenia or increased transaminases. PCR detects virus in the first week of illness or in urine up to 14 days. Serology provides a retrospective diagnosis but cross-reacts with other flaviruses. Plaque-reduction neutralisation testing can be used to detect virus-specific neutralising antibodies and distinguish between cross-reacting antibodies in primary flavivirus infections.

**Viral infections of the skin**

**Herpes simplex virus 1 and 2**

Herpes simplex viruses (HSV) cause recurrent mucocutaneous infection; HSV-1 typically involves the mucocutaneous surfaces of the head and neck (Fig. 11.14), while HSV-2 predominantly involves the genital mucosa (pp. 333 and 336), although there is overlap (see Box 11.29). The seroprevalence of HSV-1 is 30–100%, varying by socioeconomic status, while that of HSV-2 is 20–60%. Infection is acquired by inoculation of viruses shed by an infected individual onto a mucosal surface in a susceptible person. The virus infects sensory and autonomic neurons and establishes latent infection in the nerve ganglia. Primary infection is followed by episodes of reactivation throughout life.

**Clinical features**

Primary HSV-1 or 2 infection is more likely to be symptomatic later in life, causing gingivostomatitis, pharyngitis or painful genital tract lesions. The primary attack may be associated with fever and regional lymphadenopathy.

**Recurrence**

Recurrent attacks occur throughout life, most often in association with concomitant medical illness, menstruation, mechanical trauma, immunosuppression, psychological stress or, for oral lesions, ultraviolet light exposure. HSV reactivation in the oral mucosa produces the classical ‘cold sore’ or ‘herpes labialis’. Prodromal hyperaesthesia is followed by rapid vesiculation, pustulation and crusting. Recurrent HSV genital disease is a common cause of recurrent painful ulceration (pp. 333 and 336). An inoculation lesion on the finger gives rise to a paronychia, termed a ‘whitlow’, in contacts of patients with herpetic lesions (Fig. 11.14B).
Complications

Disseminated cutaneous lesions can occur in individuals with underlying dermatological diseases, such as eczema (eczema herpeticum) (Fig. 11.14C). Herpes keratitis presents with pain and blurring of vision; characteristic dendritic ulcers are visible on slit-lamp examination and may produce corneal scarring and permanent visual impairment.

Primary HSV-2 can cause meningitis or transverse myelitis. HSV is the leading cause of sporadic viral encephalitis (p. 1121); this follows either primary or secondary disease, usually with HSV-1. A haemorrhagic necrotising temporal lobe cerebritis produces temporal lobe epilepsy and altered consciousness/coma. Without treatment, mortality is 80%. HSV is also implicated in the pathogenesis of Bell’s palsy with a lower motor neuron 7th nerve palsy, although antivirals have not been demonstrated to improve outcome.

Neonatal HSV disease is usually associated with primary infection of the mother at term (see Box 11.26). In excess of two-thirds of cases develop disseminated disease with cutaneous lesions, hepatitis, pneumonitis and frequently encephalitis. Immunocompromised hosts can develop visceral disease with oesophagitis, hepatitis, pneumonitis, encephalitis or retinitis.

Diagnosis

Differentiation from other vesicular eruptions is achieved by demonstration of virus in vesicular fluid, usually by direct immunofluorescence or PCR. HSV encephalitis is diagnosed by a positive PCR for HSV in CSF. Serology is of limited value.

Management

Therapy of localised disease must commence in the first 48 hours of clinical outcome. Oral lesions in an immunocompetent individual may be treated with topical aciclovir. All severe manifestations should be treated, regardless of the time of presentation (see Box 11.30). Suspicion of HSV encephalopathy requires immediate empirical antiviral therapy. Aciclovir resistance is encountered occasionally in immunocompromised hosts, in which case foscarnet is the treatment of choice.

Human herpesvirus 8

Human herpesvirus 8 (HHV-8) (see Box 11.29) causes Kaposi’s sarcoma in both AIDS-related and endemic non-AIDS-related forms (p. 314). HHV-8 is spread via saliva, and men who have sex with men have an increased incidence of infection. Seroprevalence varies widely, being highest in sub-Saharan Africa. HHV-8 also causes two rare haematological malignancies: primary effusion lymphoma and multicentric Castleman’s disease. Current antivirals are not effective.

Enterovirus infections

Hand, foot and mouth disease

This systemic infection is caused by Coxsackie viruses usually, or occasionally by echoviruses. It affects children and occasionally adults, resulting in local or household outbreaks, particularly in the summer months. A relatively mild illness with fever and lymphadenopathy develops after an incubation period of approximately 10 days; 2–3 days later, a painful papular or vesicular rash appears on palmoplantar surfaces of hands and feet, with associated oral lesions on the buccal mucosa and tongue that ulcerate rapidly. A papular erythematous rash may appear on buttocks and thighs. Antiviral treatment is not available and management consists of symptom relief with analgesics.

Herpangina

This infection, caused by Coxsackie viruses, primarily affects children and teenagers in the summer months. It is characterised by a small number of vesicles at the soft/hard palate junction, often associated with high fever, an extremely sore throat and headache. The lesions are short-lived, rupturing after 2–3 days and rarely persisting for more than 1 week. Treatment is with analgesics if required. Culture of the virus from vesicles or DNA detection by PCR differentiates herpangina from HSV.

Poxviruses

These DNA viruses are rare but potentially important pathogens.

Smallpox (variola)

Smallpox, which has high mortality, was eradicated worldwide by a global vaccination programme but interest has re-emerged due to its potential as a bioweapon. The virus is spread by the respiratory route or contact with lesions, and is highly infectious.

The incubation period is 7–17 days. A prodrome with fever, headache and prostration leads, in 1–2 days, to the rash, which develops through macules and papules to vesicles and pustules, worst on the face and distal extremities. Lesions in one area are all at the same stage of development with no cropping (unlike chickenpox). Vaccination can lead to a modified course of disease with milder rash and lower mortality.

If a case of smallpox is suspected, national public health authorities must be contacted. Electron micrography (like Fig. 11.15) and DNA detection tests (PCR) are used to confirm diagnosis.

Monkeypox

Despite the name, the animal reservoirs for this virus are probably small squirrels and rodents. It causes a rare zoonotic infection in communities in the rainforest belt of Central Africa, producing a vesicular rash that is indistinguishable from smallpox, but differentiated by the presence of lymphadenopathy. Little person-to-person transmission occurs. Outbreaks outside

![Fig. 11.15](Image 295x82 to 480x247)
Africa have been linked to importation of African animals as exotic pets. Diagnosis is by electron micrography or DNA detection (PCR).

**Cowpox**
Humans in contact with infected cows develop large vesicles, usually on the hands or arms and associated with fever and regional lymphadenitis. The reservoir is thought to be wild rodents.

**Vaccinia virus**
This laboratory strain is the basis of the existing vaccine to prevent smallpox. Widespread vaccination is no longer recommended due to the likelihood of local spread from the vaccination site (potentially life-threatening in those with eczema (eczema vaccinatum) or immune deficiency) and of encephalitis. However, vaccination may still be recommended for key medical staff.

**Other poxviruses: orf and molluscum contagiosum**
See page 1239 and Figure 11.15.

### Gastrointestinal viral infections

#### Norovirus (Norwalk agent)
Norovirus is the most common cause of infectious gastroenteritis in the UK and leads to outbreaks in hospital wards, cruise ships and military camps. Food handlers may transmit this virus, which is relatively resistant to decontamination procedures. The incubation period is 24–48 hours. High attack rates and prominent vomiting are characteristic. Diagnosis may be achieved by electron microscopy, antigen or DNA detection (PCR) in stool samples, although the characteristic clinical and epidemiological features mean that microbiological confirmation is not always necessary. The virus is highly infectious and cases should be isolated and environmental surfaces cleaned with detergents and disinfected with bleach.

#### Astrovirus
Astroviruses cause diarrhoea in small children and occasionally in immunocompromised adults.

#### Rotavirus
Rotaviruses infect enterocytes and are a major cause of diarrhoeal illness in young children worldwide. There are winter epidemics in developed countries, particularly in nurseries. Adults in close contact with cases may develop disease. The incubation period is 48 hours and patients present with watery diarrhoea, vomiting, fever and abdominal pain. Dehydration is prominent. Diagnosis is aided by commercially available enzyme immunoassay kits, which require fresh or refrigerated stool samples. Immunity develops to natural infection. Monovalent and multivalent vaccines have been licensed in many countries and have now demonstrated efficacy in large trials in Africa and the Americas.

#### Hepatitis viruses (A–E)
See Chapter 22.

#### Other viruses
Adenoviruses are frequently identified from stool culture and implicated as a cause of diarrhoea in children. They have also been linked to cases of intussusception.

### Respiratory viral infections

These infections are described on page 581.

Adenoviruses, rhinoviruses and enteroviruses (Coxsackie viruses and echoviruses) often produce non-specific upper respiratory tract symptoms but may cause viral pneumonia. Parainfluenza and respiratory syncytial viruses cause upper respiratory tract disease, croup and bronchiolitis in small children and pneumonia in the immunocompromised. Respiratory syncytial virus also causes pneumonia in nursing home residents and may be associated with nosocomial pneumonia. Metapneumovirus and bocavirus cause upper and occasionally lower respiratory tract infection, especially in immunosuppressed individuals. The severe acute respiratory syndrome (SARS), caused by the SARS coronavirus, emerged as a major respiratory pathogen during an outbreak in 2002–2003, with 8000 cases and 10% mortality (p. 582).

### Middle East respiratory syndrome coronavirus (MERS-CoV)

In 2012, a novel coronavirus, distantly related to the SARS coronavirus, caused several deaths connected with pneumonia in patients originating from the Middle East. The Middle East respiratory syndrome coronavirus (MERS-CoV) appears to be a zoonosis, involving transmission from bats to camels and then to humans. Over 20 countries have reported cases, although most cases have a history of travel to Saudi Arabia or other countries in the Arabian Peninsula. By 2016 there had been over 1700 reported cases.

#### Clinical features
The incubation period in person-to-person transmission is 2–14 (average 5) days. Any age may be infected but the severe form of MERS-CoV mainly occurs in patients over 50 with medical comorbidities. Initial symptoms are fever, chills, headache, myalgia, dry cough and dyspnoea. Abdominal pain and diarrhoea may be prominent. The mean period from symptom onset to hospitalisation is 4 days, and 5 days to intensive care unit admission. Illness is complicated by rapid development of respiratory failure and features of ARDS and multi-organ failure. Mortality is 35%.

#### Diagnosis and management
Laboratory features include lymphopenia, thrombocytopenia and raised lactate dehydrogenase (LDH). Diagnosis is confirmed by PCR of serum, nasopharyngeal or other respiratory samples. Serology may also be useful. Treatment is supportive. Strict infection control measures should be implemented for anyone with fever, severe respiratory illness and epidemiological risk factors. Patients should be managed in an airborne infection isolation room with contact and airborne infection control measures, including personal protective equipment for health-care workers.

### Viral infections with neurological involvement

See also page 1121.

### Japanese B encephalitis

This flavivirus is an important cause of endemic encephalitis in Japan, China, Russia, South-east Asia, India and Pakistan; outbreaks also occur elsewhere. There are 10 000–20 000 cases reported to the WHO annually. Pigs and aquatic birds are the
virus reservoirs and transmission is by mosquitoes. Exposure to rice paddies is a recognised risk factor.

**Clinical features**

The incubation period is 4–21 days. Most infections are subclinical in childhood and 1% or less of infections lead to encephalitis. Initial systemic illness with fever, malaise and anorexia is followed by headache, photophobia, vomiting and changes in brainstem function. Other neurological features include meningism, seizures, cranial nerve palsies, flaccid or spastic paralysis and extrapyramidal syndromes. Mortality with neurological disease is 25%. Most children die from respiratory failure. Some 50% of survivors have neurological sequelae.

**Investigations, management and prevention**

Other infectious causes of encephalitis should be excluded (p. 1121). There is neutrophilia and often hyponatraemia. CSF analysis reveals lymphocytosis and elevated protein. Serological testing of serum and CSF aids diagnosis but may cross-react with dengue and other flaviviruses.

Treatment is supportive. Vaccination is recommended for travellers to endemic areas during the monsoon. Some endemic countries include vaccination in their childhood schedules.

---

**West Nile virus**

This flavivirus is an important cause of neurological disease in an area that extends from Australia, India and Russia through Africa and Southern Europe and across to North America. The disease has an avian reservoir and a mosquito vector. Older people are at increased risk of neurological disease.

**Clinical features**

Most infections are asymptomatic. After 2–6 days’ incubation, a mild febrile illness and arthralgia may occur. A prolonged incubation may be seen in immunocompromised individuals. Children may develop a maculopapular rash. Neurological disease is seen in 1% and is characterised by encephalitis, meningitis or asymmetric flaccid paralysis with 10% mortality.

**Diagnosis and management**

Diagnosis is by serology or detection of viral RNA in blood or CSF. Serological tests may show cross-reactivity with other flaviviruses, including vaccine strains. Treatment is supportive.

---

**Enterovirus 71**

Enterovirus 71 has caused outbreaks around the globe of enteroviral disease with hand, foot and mouth disease (p. 248) and aseptic meningitis. Some cases have been complicated by encephalitis with flaccid paralysis or by brainstem involvement and death. The virus can be isolated from vesicle fluid, stool or CSF, and viral RNA can be detected in CSF by RT-PCR.

---

**Nipah virus encephalitis**

Nipah virus is a paramyxovirus in the Henipavirus genus, which caused an epidemic of encephalitis amongst Malaysian pig farmers in 1999 and subsequently caused outbreaks in Bangladesh and India. Mortality is around 30%. Diagnosis is by PCR or serology.

---

**Human T-cell lymphotropic virus type I**

Human T-cell lymphotropic virus type I (HTLV-1) is a retrovirus that causes chronic infection with development of adult T-cell leukaemia/lymphoma (ATL) or HTLV-1-associated myelopathy (HAM) in a subset of those infected (see Box 23.57, p. 964). It is found mainly in Japan, the Caribbean, Central and South America, and the Seychelles. HAM or tropical spastic paraparesis occurs in less than 5% of those with chronic infection, and presents with gait disturbance, spasticity of the lower extremities, urinary incontinence, impotence and sensory disturbance. Myositis and uveitis may also occur with HTLV-1 infection. Serology, sometimes confirmed with PCR, establishes the diagnosis. Treatment is usually supportive.

---

**Viral infections with rheumatological involvement**

Rheumatological syndromes characterise a variety of viral infections ranging from exanthems, such as rubella and parvovirus B19 (p. 237), to blood-borne viruses, such as HBV and HIV-1 and the sequelae of EVD.

**Chikungunya virus**

Chikungunya is an alphavirus that causes fever, rash and arthropathy. It is found principally in Africa and Asia, including India. Humans and non-human primates are the main reservoir and the main vector is the *Aedes aegypti* mosquito. Cases occur in epidemics on a background of sporadic cases. In 2007, an outbreak extended as far north as Italy.

The incubation period is 2–12 days. A period of fever may be followed by an afebrile phase and then recrudescence of fever. Children may develop a maculopapular rash. Adults are susceptible to arthritis, which causes early morning pain and swelling, most often in the small joints. Arthritis can persist for months and may become chronic in individuals who are positive for human leucocyte antigen (HLA)-B27. Related alphaviruses causing similar syndromes include Sindbis virus (Scandinavia and Africa), O’nyong-nyong virus (Central Africa), Ross River virus (Australia) and Mayaro virus (Caribbean and South America).

Diagnosis is by serology but cross-reactivity between alphaviruses occurs. Treatment is symptomatic.

---

**Prion diseases**

Prions cause transmissible spongiform encephalopathies and are discussed on page 1126.

---

**Bacterial infections**

**Bacterial infections of the skin, soft tissues and bones**

Most infections of the skin, soft tissues and bone are caused by either *Staph. aureus* or streptococci (mainly *Strep. pyogenes*) (see pp. 1019 and 1237).

**Staphylococcal infections**

Staphylococci are usually found colonising the anterior nares and skin. Some staphylococci produce coagulase, an enzyme that converts fibrinogen to fibrin in rabbit plasma, causing it to clot. *Staph. aureus* is coagulase-positive, and most other species are coagulase-negative. In modern laboratory practice, however, the identification of *Staph. aureus* rarely involves the coagulase test.
Staphylococci are particularly dangerous if they gain access to the blood stream, having the potential to disseminate widely (Fig. 11.16). In any patient with staphylococcal bacteraemia, especially injection drug-users, the possibility of endocarditis must be considered (p. 527). Growth of *Staph. aureus* in blood cultures should not be dismissed as a ‘contaminant’ unless all possible underlying sources have been excluded and repeated blood culture is negative. Any evidence of spreading cellulitis indicates the urgent need for an antistaphylococcal antibiotic, such as flucloxacillin (unless there is a likely risk of MRSA). This is particularly true for mid-facial cellulitis, which can result in cavernous sinus thrombophlebitis.

In addition, *Staph. aureus* can cause severe systemic disease due to the effects of toxin produced at superficial sites in the absence of tissue invasion by bacteria.

**Skin infections**

Staphylococcal infections cause ecthyma, folliculitis, furuncles, carbuncles, bullous impetigo and the scalded skin syndrome (pp. 1235–1237). They may also be involved in necrotising infections of the skin and subcutaneous tissues (p. 226).

**Wound infections**

Many wound infections are caused by staphylococci, which may significantly prolong post-operative hospital stays.

forming a biofilm on cannulae, which remains as a source of bacteraemia. Local poultice application may relieve symptoms but cannula removal and antibiotic treatment with flucloxacillin (or a glycopeptide if MRSA is suspected) are necessary if there is any suggestion of spreading infection.

**Meticillin-resistant Staph. aureus**

Resistance to meticillin is due to a penicillin-binding protein mutation in *Staph. aureus*. Resistance to vancomycin/teicoplanin (glycopeptides) in either glycopeptide intermediate *Staph. aureus* (GISA) or, rarely, vancomycin-resistant (VRSA) strains threatens the ability to manage serious infections produced by such organisms. Meticillin-resistant *Staph. aureus* (MRSA) is now a major worldwide health care-acquired pathogen, accounting for up to 40% of staphylococcal bacteraemia in developed countries. Community-acquired MRSA (c-MRSA) currently accounts for 50% of all MRSA infections in the USA. These organisms have also acquired other toxins, such as Panton–Valentine leukocidin (PVL), and cause rapidly fatal infection in young people. Clinicians must be aware of the potential danger of these infections and be prepared to take whatever appropriate infection control measures are locally advised (p. 111).

Treatment options for MRSA are shown in Box 6.16 (p. 117). Treatment should always be based on the results of antimicrobial susceptibility testing, since resistance to all these agents occurs. Milder MRSA infections may be treated with clindamycin, tetracyclines or co-trimoxazole. Glycopeptides, linezolid and daptomycin are reserved for treatment of more severe infections. Toxin-producing MRSA infections should be treated with protein-inhibiting antibiotics (clindamycin, linezolid).

**Staphylococcal toxic shock syndrome**

Staphylococcal toxic shock syndrome (TSS) is a serious and life-threatening disease associated with infection by *Staph. aureus*, which produces a specific toxin (toxic shock syndrome toxin 1, TSST1). It was formerly seen in young women in association with the use of highly absorbent intravaginal tampons but can occur with any *Staph. aureus* infection involving a relevant toxin-producing strain. The toxin acts as a ‘super-antigen’, triggering significant T-cell activation and massive cytokine release.

TSS has an abrupt onset with high fever, generalised systemic upset (myalgia, headache, sore throat and vomiting), a widespread erythematous blanching rash resembling scarlet fever, and hypotension. It rapidly progresses over a few hours to multi-organ failure, leading to death in 10–20%. Recovery is accompanied at 7–10 days by desquamation (Fig. 11.18).

The diagnosis is clinical and may be confirmed in menstrual cases by finding a retained tampon with staphylococci on Gram stain. Subsequent culture and demonstration of toxin production are confirmatory.

**Management**

Treatment is with immediate and aggressive fluid resuscitation and an intravenous antistaphylococcal antimicrobial (flucloxacillin or vancomycin), usually with the addition of a protein synthesis inhibitor (e.g. clindamycin) to inhibit toxin production. Intravenous immunoglobulin is occasionally added in the most severe cases. Women who recover from tampon-associated TSS should avoid tampons for at least 1 year and be advised that the condition can recur.

**Streptococcal infections**

Streptococci are oropharyngeal and gut commensals, which appear as Gram-positive cocci in chains (see Fig. 6.3, p. 102). They are classified by the pattern of haemolysis they produce on blood agar (see Fig. 6.4, p. 102), by their ‘Lancefield groups’ (Box 11.38) and more recently by speciation on matrix-assisted laser desorption/ionisation time-of-flight (MALDI-TOF) mass spectrometry. Some streptococci (e.g. *Strept. milleri* group) defy simple classification.

Group A streptococci (GAS) are the leading cause of bacterial pharyngitis. Although the presence of fever, tender anterior lymphadenopathy and purulent tonsillar exudate and the absence of cough make streptococcal pharyngitis more likely than viral infection, clinical features alone are unreliable for diagnosing streptococcal pharyngitis. GAS are also the major cause of cellulitis, erysipelas and impetigo (pp. 1237 and 1235). Groups C and G streptococci cause cellulitis, particularly in elderly, diabetic or immunocompromised patients. Group B streptococci (GBS) colonise the gut and vagina. They cause post-partum and neonatal sepsis, as well as other deep infections (infective endocarditis, septic arthritis, osteomyelitis etc.), especially in the elderly.

**Streptococcal scarlet fever**

Group A (or occasionally groups C and G) streptococci causing pharyngitis, tonsillitis or other infection may lead to scarlet fever, if the infecting strain produces a streptococcal pyrogenic exotoxin. Scarlet fever is most common in school-age children, but can also occur in young adults who have contact with young children. A diffuse erythematous rash occurs, which blanches on pressure (Fig. 11.19A), classically with circumoral pallor. The tongue, initially coated, becomes red and swollen (‘strawberry tongue’, Fig. 11.19B). The disease lasts about 7 days, the rash disappearing in 7–10 days, followed by a fine desquamation. Residual petechial lesions in the antecubital fossa may be seen (‘Pastia’s sign’, Fig. 11.19C).

Treatment involves intravenous benzylpenicillin or an oral penicillin plus symptomatic measures.

N.B. All streptococci can cause sepsis.

Streptococcal toxic shock syndrome

Group A (or occasionally group C or G) streptococci can produce one of a variety of toxins, such as pyogenic exotoxin A. Like staphylococcal TSST1 (see above), these act as super-antigens. Initially, an influenza-like illness occurs, with signs of localised infection in 50% of cases, most often involving the skin and soft tissues. A faint erythematous rash, mainly on the chest, rapidly progresses to circulatory shock. Without aggressive management, multi-organ failure will develop.

Fluid resuscitation must be undertaken, along with parenteral antistreptococcal antibiotic therapy, usually with benzylpenicillin and clindamycin, to inhibit toxin production. Intravenous immunoglobulin is often administered. If necrotising fasciitis is present, it should be treated as described on page 227 with urgent débridement.

Treponematoses

Syphilis

This disease is described on page 337.

Endemic treponematoses

Yaws

Yaws is a granulomatous disease, mainly involving the skin and bones; it is caused by Treponema pertenue, morphologically and serologically indistinguishable from the causative organisms of syphilis and pinta. It is important to establish the geographical origin and sexual history of patients to exclude false-positive syphilis serology due to endemic treponemal infections. Between 1950 and 1960, WHO campaigns treated over 60 million people and eradicated yaws from many areas, but the disease has persisted patchily throughout the tropics; there was a resurgence in the 1980s and 1990s in West and Central Africa and the South Pacific.

Organisms are transmitted by bodily contact from a patient with infectious yaws through minor abrasions of the skin of another patient, usually a child. After an incubation period of 3–4 weeks, a proliferative granuloma containing numerous treponemes develops at the site of inoculation. This primary lesion is followed by secondary eruptions. In addition, there may be hypertrophic periosteal lesions of many bones, with underlying cortical rarefaction. Lesions of late yaws are characterised

Fig. 11.19 Clinical features of scarlet fever. A Characteristic rash with blanching on pressure. B Strawberry tongue. C Pastia’s sign: a petechial rash in the cubital fossa.
by destructive changes that closely resemble the osteitis and gummas of tertiary syphilis and that heal with scarring and deformity. Investigations and management are outlined in Box 11.39. Improved housing and hygiene, combined with mass chemotherapy programmes, have achieved dramatic success in the control of yaws.

Pinta and bejel

These two treponemal infections occur in poor rural populations with low standards of domestic hygiene but are found in separate parts of the world. They have features in common, notably that they are transmitted by contact, usually within the family and not sexually, and in the case of bejel, through common eating and drinking utensils. Their diagnosis and management are as for yaws (Box 11.39).

- **Pinta.** Pinta is found only in South and Central America, where its incidence is declining. The infection is confined to the skin. The early lesions are scaly papules or dyschromic patches on the skin. The late lesions are often depigmented and disfiguring.

- **Bejel.** Bejel is the Middle Eastern name for non-venereal syphilis, which has a patchy distribution across sub-Saharan Africa, the Middle East, Central Asia and Australia. It has been eradicated from Eastern Europe. Transmission is most commonly from the mouth of the mother or child and the primary mucosal lesion is seldom seen. The early and late lesions resemble those of secondary and tertiary syphilis (p. 337) but cardiovascular and neurological disease is rare.

**Tropical ulcer**

Tropical ulcer is due to a synergistic bacterial infection caused by a fusobacterium (*F. ulcerans*, an anaerobe) and *Treponema vincentii*. It is common in hot, humid regions. The ulcer is most common on the lower legs and develops as a papule that rapidly breaks down to a sharply defined, painful ulcer. The base of the ulcer has a foul slough. Penicillin and metronidazole are useful in the early stages but rest, elevation and dressings are the mainstays of treatment.

**Buruli ulcer**

This ulcer is caused by *Mycobacterium ulcerans* and occurs widely in tropical rainforests. In 1999, a survey in Ghana found 6500 cases; there are an estimated 10,000 cases in West Africa as a whole.

The initial lesion is a small subcutaneous nodule on the arm or leg. This breaks down to form a shallow, necrotic ulcer with deeply undermined edges, which extends rapidly. Healing may occur after 6 months but granuloma formation and the accompanying fibrosis cause contractures and deformity. Clumps of acid-fast bacilli can be detected in the ulcer floor.

A combination of rifampicin and streptomycin can cure the infection. Infected tissue should be removed surgically. Health campaigns in Ghana have successfully focused on early removal of the small, pre-ulcerative nodules.

### Systemic bacterial infections

#### Brucellosis

*Brucella* spp. are intracellular organisms that survive for long periods within the reticulo-endothelial system. This explains the disease chronicity and tendency to relapse, even after antimicrobial therapy.

Acute illness is characterised by a high swinging temperature, rigors, lethargy, headache, joint and muscle pains, and scrotal pain. Occasionally, there is delirium, abdominal pain and constipation. Physical signs are non-specific, e.g. enlarged lymph nodes. Splenomegaly may cause thrombocytopenia.

Localised infection (Fig. 11.20), which occurs in about 30% of patients, is more likely if diagnosis and treatment are delayed.

**Diagnosis**

Definitive diagnosis depends on culture of the organism. Blood cultures are positive in 75–80% of *B. melitensis* and 50% of *B. abortus* infections. Bone marrow culture is not routine but may increase the diagnostic yield if antibiotics have been used prior to culture. CSF culture in neurobrucellosis is positive in about 30% of cases. The laboratory should be alerted to a suspected diagnosis of brucellosis, as the organism may infect laboratory workers and must be cultured at the appropriate biosafety level.

Serology may also aid diagnosis. In endemic areas, a single high antibody titre of more than 1/320 or a fourfold rise in titre is needed to support a diagnosis of acute infection. The test usually takes several weeks to become positive but should eventually detect 95% of acute infections.

**Management**

Aminoglycosides show synergistic activity with tetracyclines against *brucellae*. Treatment regimens for different forms of brucellosis are outlined in Box 11.40.
Bacterial infections

Borrelia infections

Borrelia are flagellated spirochaetal bacteria that infect humans after bites from ticks or lice. They cause a variety of human infections worldwide (Box 11.41).

Lyme disease

Lyme disease (named after the town of Old Lyme in Connecticut, USA) is caused by *B. burgdorferi*, which occurs in the USA, Europe, Russia, China, Japan and Australia. In Europe, two additional genospecies are also encountered, *B. afzelii* and *B. garinii*. The reservoir of infection is ixodid (hard) ticks that feed on a variety of large mammals, particularly deer. Birds may spread ticks over a wide area. The organism is transmitted to humans via the bite of infected ticks; larval, nymphal and adult forms are all capable of spreading infection.

Ehrlichiosis is a common co-infection with Lyme disease. Two forms occur: *Anaplasma phagocytophilum*, human granulocytic anaplasmosis (HGA); and *Ehrlichia chaffeensis*, human monocytic ehrlichiosis (HME).

Clinical features

There are three stages of disease. Progression may be arrested at any stage.

- **Early localised disease**: The characteristic feature is a skin reaction around the site of the tick bite, known as erythema migrans (Fig. 11.21). Initially, a red ‘bull’s eye’ macule or papule appears 2–30 days after the bite. It then enlarges peripherally with central clearing and may persist for months. Atypical forms are common. The lesion is not pathognomonic of Lyme disease since similar lesions can occur after tick bites. Acute manifestations, such as fever, headache and regional lymphadenopathy, may develop with or without the rash.
Initial infection. Carditis, sometimes accompanied by atrioventricular conduction defects, occurs in the USA but is rare in Europe.

**Late disease.** Late manifestations include arthritis, polyneuritis and encephalopathy. Prolonged arthritis, particularly affecting large joints, and brain parenchymal involvement, causing neuropsychiatric abnormalities, may occur but are rare in the UK. Acrodermatitis chronica atrophicans is an uncommon late complication seen more frequently in Europe than North America. Doughy, patchy discoloration occurs on the peripheries, eventually leading to shiny atrophic skin. The lesions are easily mistaken for those of peripheral vascular disease. In patients coming from an endemic area or having risk factors, who have facial nerve palsy, Lyme disease should be considered.

**Diagnosis**

The diagnosis of early Lyme borreliosis is often clinical. Culture from biopsy material is not generally available, has a low yield and may take longer than 6 weeks. Antibody detection is frequently negative early in the course of the disease but sensitivity increases to 90–100% in disseminated or late disease. Immunofluorescence or ELISA can give false-positive reactions in a number of conditions, including other spirochaetal infections, infectious mononucleosis, rheumatoid arthritis and systemic lupus erythematosus (SLE). Immunoblot (Western blot) techniques are more specific and, although technically demanding, should be used to confirm the diagnosis. Microorganism DNA detection by PCR has been applied to blood, urine, CSF and biopsies of skin and synovium.

**Management**

Recent evidence suggests that asymptomatic patients with positive antibody tests should not be treated. However, erythema migrans always requires therapy because organisms may persist and cause progressive disease, even if the skin lesions resolve. Standard therapy consists of a 14-day course of doxycycline (200 mg daily) or amoxicillin (500 mg 3 times daily). Some 15% of patients with early disease will develop a mild Jarisch–Herxheimer reaction (JHR) during the first 24 hours of therapy (p. 339). In pregnant women and small children with penicillin allergy, or in those allergic to amoxicillin and doxycycline, 14-day treatment with cefuroxime axetil (500 mg twice daily) or erythromycin (250 mg 4 times daily) may be used.

Disseminated disease and arthritis require therapy for a minimum of 28 days. Arthritis may respond poorly and prolonged or repeated courses may be necessary. Neuroborreliosis is treated with parenteral β-lactam antibiotics for 3–4 weeks; third-generation cephalosporins such as ceftriaxone are the preferred therapy.

**Prevention**

Protective clothing and insect repellents should be used in tick-infested areas. Since the risk of borrelial transmission is lower in the first few hours of a blood feed, prompt removal of ticks is advisable. Unfortunately, larval and nymphal ticks are tiny and may not be noticed. Where risk of transmission is high, a single 200 mg dose of doxycycline, given within 72 hours of exposure, has been shown to prevent erythema migrans.
**Louse-borne relapsing fever**

The human body louse, *Pediculus humanus*, causes itching. *Borreliae* (*B. recurrentis*) are liberated from infected lice when they are crushed during scratching, which also inoculates the borreliae into the skin. The disease occurs worldwide, with epidemic relapsing fever most often seen in Central/East Africa and South America.

The borreliae multiply in the blood, where they are abundant in the febrile phases, and invade most tissues, especially the liver, spleen and meninges.

**Clinical features**

Onset is sudden with fever. The temperature rises to 39.5–40.5°C, accompanied by a tachycardia, headache, generalised aching, injected conjunctivae (Fig. 11.22) and herpes labialis. Thrombocytopenia is associated with a petechial rash and epistaxis. As the disease progresses tender hepatosplenomegaly, delirium and meningism. The fever ends in crisis between the fourth and tenth days, often associated with profuse sweating, hypotension and circulatory and cardiac failure. There may be no further fever but, in a proportion of patients, after an afebrile period of about 7 days, there are one or more relapses, which are usually milder and less prolonged. In the absence of specific treatment, the mortality rate is up to 40%, especially among the elderly and malnourished.

**Investigations and management**

Dark ground microscopy of a wet film or Wright-Giemsa stained thick and thin films demonstrate the organism in blood from a febrile patient.

Treatment aims to eradicate the organism and prevent relapses, while minimising the severe JHR that inevitably follows successful chemotherapy. The safest treatment is procaine penicillin 300 mg IM, followed the next day by 0.5 g tetracycline. Tetracycline alone is effective and prevents relapse, but may give rise to a worse reaction. Doxycycline 200 mg once orally in place of tetracycline has the advantage of also being curative for JHR is best managed in a high-dependency unit with expert nursing and medical care.

The patient, clothing and all contacts must be freed from lice, as in epidemic typhus.

![Fig. 11.22 Louse-borne relapsing fever. Injected conjunctivae.](image)

**Tick-borne relapsing fever**

Soft ticks (*Ornithodoros* spp.) transmit *B. duttonii* (and other *Borrelia* species) through saliva while feeding on their host. People sleeping in mud houses are at risk, as the tick hides in crevices during the day and feeds on humans during the night. Rodents are the reservoir in all parts of the world except East Africa, where humans are the reservoir. Clinical manifestations are similar to those seen with the louse-borne disease but microorganisms are detected in fewer patients on dark field microscopy. A 7-day course (due to a higher relapse rate than in louse-borne relapsing fever) of treatment with either tetracycline (500 mg 4 times daily) or erythromycin (500 mg 4 times daily) is needed.

**Leptospirosis**

Leptospirosis is one of the most common zoonotic diseases, favoured by a tropical climate and flooding during the monsoon but occurring worldwide. Leptospires are tightly coiled, thread-like organisms about 5–7 μm in length, which are actively motile; each end is bent into a hook. *Leptospira interrogans* is pathogenic for humans. The genus can be separated into more than 200 serovars (subtypes) belonging to 23 serogroups.

Leptospirosis appears to be ubiquitous in wildlife and in many domestic animals. The organisms persist indefinitely in the convoluted tubules of the kidney and are shed into the urine in massive numbers, but infection is asymptomatic in the host. The most frequent hosts are rodents, especially the common rat (*Rattus norvegicus*). Particular leptosomal serogroups are associated with characteristic animal hosts; for example, *L. icterohaemorrhagiae* is the classical parasite of rats and *L. canicola* of dogs. There is nevertheless considerable overlap in host–serogroup associations.

Leptospires can enter their human hosts through intact skin or mucous membranes but entry is facilitated by cuts and abrasions. Prolonged immersion in contaminated water will also favour invasion, as the spirochaete can survive in water for months. Leptospirosis is common in the tropics and also in freshwater sports enthusiasts.

**Clinical features**

After a relatively brief bacteraemia, invading organisms are distributed throughout the body, mainly in kidneys, liver, meninges and brain. The incubation period averages 1–2 weeks. Four main clinical syndromes can be discerned and clinical features can involve multiple different organ systems (Fig. 11.23).

**Bacteraemic leptospirosis**

Bacteraemia with any serogroup can produce a non-specific illness with high fever, weakness, muscle pain and tenderness (especially of the calf and back), intense headache and photophobia, and sometimes diarrhoea and vomiting. Conjunctival congestion is the only notable physical sign. The illness comes to an end after about 1 week, or else merges into one of the other forms of infection.

**Aseptic meningitis**

Classically associated with *L. canicola* infection, this illness is very difficult to distinguish from viral meningitis. The conjunctivae may be congested but there are no other differentiating signs. Laboratory clues include a neutrophil leucocytosis, abnormal LFTs, and the occasional presence of albumin and casts in the urine.
Icteric leptospirosis (Weil’s disease)

Fewer than 10% of symptomatic infections result in severe icteric illness. Weil’s disease is a dramatic life-threatening event, characterised by fever, haemorrhages, jaundice and acute kidney injury. Conjunctival hyperaemia is a frequent feature. The patient may have a transient macular erythematous rash but the characteristic skin changes are purpura and large areas of bruising. In severe cases there may be epistaxis, haematemesis and melaena, or bleeding into the pleural, pericardial or subarachnoid spaces. Thrombocytopenia, probably related to activation of endothelial cells with platelet adhesion and aggregation, is present in 50% of cases. Jaundice is deep and the liver is enlarged but there is usually little evidence of hepatic failure or encephalopathy. Acute kidney injury, primarily caused by impaired renal perfusion and acute tubular necrosis, manifests as oedema or anuria, with the presence of albumin, blood and casts in the urine.

Weil’s disease may also be associated with myocarditis, encephalitis and aseptic meningitis. Uveitis and iritis may appear months after apparent clinical recovery.

Pulmonary syndrome

This syndrome has long been recognised in the Far East and has been described during an outbreak of leptospirosis in Nicaragua. It is characterised by haemoptysis, patchy lung infiltrates on chest X-ray, and respiratory failure. Total bilateral lung consolidation and ARDS (p. 324) with multi-organ dysfunction may develop, with a high mortality (over 50%).

Diagnosis

A polymorphonuclear leucocytosis is accompanied in severe infection by thrombocytopenia and elevated blood levels of creatine kinase. In jaundiced patients, there is hepatitis and the prothrombin time may be prolonged. The CSF in leptospiro-meningitis shows a variable cellular response, a moderately elevated protein level and normal glucose content. Acute kidney injury due to interstitial nephritis is common.

In the tropics, dengue, malaria, typhoid fever, scrub typhus and hantavirus infection are important differential diagnoses. Definitive diagnosis of leptospirosis depends on isolation of the organism, serological tests or detection of specific DNA. In general, however, it is probably under-diagnosed.

- Blood cultures are most likely to be positive if taken before the 10th day of illness. Special media are required and cultures may have to be incubated for several weeks.
- Leptospires appear in the urine during the second week of illness, and in untreated patients may be recovered on culture for several months.
- Serological tests are diagnostic if seroconversion or a fourfold increase in titre is demonstrated. The microscopic agglutination test (MAT) is the investigation of choice and can become positive by the end of the first week. IgM ELISA and immunofluorescent techniques are easier to perform, however, while rapid immunochromatographic tests are specific but of only moderate sensitivity in the first week of illness.
- Detection of leptospiral DNA by PCR is possible in blood in early symptomatic disease, and in urine from the eighth day of illness and for many months thereafter.

Management and prevention

The general care of the patient is critically important. Blood transfusion for haemorrhage and careful attention to renal function, the usual cause of death, are especially important. Acute kidney injury is potentially reversible with adequate support, such as dialysis. Most infections are self-limiting. Therapy with either oral doxycycline (100 mg twice daily for 1 week) or intravenous penicillin (900 mg 4 times daily for 1 week) is effective but may not prevent the development of renal failure. Parenteral ceftriaxone (1 g daily) is as effective as penicillin. JHR may occur but is usually
mild. Uveitis is treated with a combination of systemic antibiotics and local glucocorticoids. There is no role for the routine use of glucocorticoids in the management of leptospirosis.

Trials in military personnel have shown that infection with *L. interrogans* can be prevented by taking prophylactic doxycycline 200 mg weekly.

## Plague

Plague is caused by *Yersinia pestis*, a small Gram-negative bacillus that is spread between rodents by their fleas. If domestic rats become infected, infected fleas may bite humans. Hunters and trappers can contract plague from handling rodents. In the late stages of human plague, *Y. pestis* may be expectorated and spread between humans by droplets, causing ‘pneumonic plague’.

Epidemics of plague, such as the ‘Black Death’, have occurred since ancient times. It is often said that the first sign of plague is the appearance of dead rats. Plague foci are widely distributed throughout the world, including the USA; human cases are reported from about 10 countries per year (Fig. 11.24).

*Y. pestis* is a potential bioweapon because of the possibility of person-to-person spread and the high fatality rate associated with pneumonic plague.

### Clinical features

Organisms inoculated through the skin are transported rapidly to the draining lymph nodes, where they elicit a severe inflammatory response that may be haemorrhagic. If the infection is not contained, sepsis ensues and necrotic, purulent or haemorrhagic lesions develop in many organs. Oliguria and shock follow, and disseminated intravascular coagulation may result in widespread haemorrhage. Inhalation of *Y. pestis* causes alveolitis. The incubation period is 3–6 days but shorter in pneumonic plague.

#### Bubonic plague

In this, the most common form of the disease, onset is usually sudden, with a rigor, high fever, dry skin and severe headache. Soon, aching and swelling at the site of the affected lymph nodes begin. The groin is the most common site of this ‘bubo’, made up of the swollen lymph nodes and surrounding tissue. Some infections are relatively mild but, in the majority of patients, toxaemia quickly increases, with a rapid pulse, hypotension and delirium. The spleen is usually palpable.

#### Septicaemic plague

Those not exhibiting a bubo usually deteriorate rapidly and have a high mortality. The elderly are more prone to this form of illness.

### Management

If the diagnosis is suspected on clinical and epidemiological grounds, treatment must be started as soon as, or even before, samples have been collected for laboratory diagnosis. Streptomycin (1 g twice daily) or gentamicin (1 mg/kg 3 times daily) is the drug of choice. Tetracycline (500 mg 4 times daily) and chloramphenicol (12.5 mg/kg 4 times daily) are alternatives. Fluoroquinolones (ciprofloxacin and levofloxacin) may be as effective but there is less clinical experience. Treatment may also be needed for acute circulatory failure, DIC and hypoxia.

#### Prevention and infection control

Rats and fleas should be controlled. In endemic areas, people should avoid handling and skinning wild animals. The patient should be isolated for the first 48 hours or until clinical improvement begins. Attendants must wear gowns, masks and gloves. Exposed symptomatic or asymptomatic people who have been in close contact with a patient with pneumonic plague should receive post-exposure antibiotic prophylaxis (doxycycline 100 mg or ciprofloxacin 500 mg twice daily) for 7 days.

A recombinant subunit vaccine (protein antigens F1 + V) is in development.

### Listeriosis

*Listeria monocytogenes* is an environmental Gram-positive bacillus that can contaminate food. Outbreaks have been associated with raw vegetables, soft cheeses, under-cooked chicken, fish, meat and pâtés. The bacterium demonstrates ‘cold enrichment’, outgrowing other contaminating bacteria during refrigeration. Although food-borne outbreaks of gastroenteritis have been reported in immunocompetent individuals, *Listeria* causes more significant invasive infection, especially in pregnant women, older adults (over 55 years) and the immunocompromised.
In pregnancy, in addition to systemic symptoms of fever and myalgia, listeriosis causes chorioamnionitis, fetal deaths, abortions and neonatal infection. In other susceptible individuals, it causes systemic illness due to bacteraemia without focal symptoms. Meningitis, similar to other bacterial meningitis but with normal CSF glucose, is the next most common presentation; CSF usually shows increased neutrophils but occasionally only the mononuclear cells are increased (see Box 25.6, p. 1078).

**Investigations and management**

Diagnosis is made by blood and CSF culture. The organism grows readily in culture media.

The most effective regimen consists of a combination of intravenous amoxicillin or ampicillin plus an aminoglycoside. A sulfamethoxazole/trimethoprim combination can be used in those with penicillin allergy. Cephalosporins are of no use in this infection, as the organism is inherently resistant, an important consideration when treating meningitis empirically.

Proper treatment of foods before eating is the key to preventing listeriosis. Pregnant women are advised to avoid high-risk products, including soft cheeses.

### Typhoid and paratyphoid (enteric) fevers

Typhoid and paratyphoid fevers, which are transmitted by the faecal–oral route, are important causes of fever in the Indian subcontinent, sub-Saharan Africa and Latin America. Elsewhere, they are relatively rare. Enteric fevers are caused by infection with *Salmonella Typhi* and *Salmonella Paratyphi A and B*. After a few days of bacteraemia, the bacilli localise, mainly in the lymphoid tissue of the small intestine, resulting in typical lesions in the Peyer’s patches and follicles. These swell at first, then ulcerate and usually heal. After clinical recovery, about 5% of patients become chronic carriers (i.e. continue to excrete the bacteria after 1 year); the bacilli may live in the gallbladder for months or years and pass intermittently in the stool and, less commonly, in the urine.

**Clinical features**

#### Typhoid fever

Clinical features are outlined in Box 11.42. The incubation period is typically about 10–14 days but can be longer, and the onset may be insidious. The temperature rises in a stepladder fashion for 4 or 5 days with malaise, increasing headache, drowsiness and aching in the limbs. Constipation may be caused by swelling of lymphoid tissue around the ileocaecal junction, although in children diarrhoea and vomiting may be prominent early in the illness. The pulse is often slower than would be expected from the height of the temperature, i.e. a relative bradycardia.

At the end of the first week, a rash may appear on the upper abdomen and on the back as sparse, slightly raised, rose-red spots, which fade on pressure. It is usually visible only on white skin. Cough and epistaxis occur. Around the 7th–10th day, the spleen becomes palpable. Constipation is followed by diarrhoea and abdominal distension with tenderness. Bronchitis and delirium may develop. If untreated, by the end of the second week the patient may be profoundly ill.

#### Paratyphoid fever

The course tends to be shorter and milder than that of typhoid fever and the onset is often more abrupt with acute enteritis. The rash may be more abundant and the intestinal complications less frequent.

**Complications**

These are given in Box 11.43. Haemorrhage from, or a perforation of, the ulcerated Peyer’s patches may occur at the end of the second week or during the third week of the illness. A drop in temperature to normal or subnormal levels may be falsely reassuring in patients with intestinal haemorrhage. Additional complications may involve almost any viscus or system because of the bacteraemia present during the first week. Bone and joint infection is common in children with sickle-cell disease.

#### Investigations

In the first week, diagnosis may be difficult because, in this invasive stage with bacteraemia, the symptoms are those of a generalised infection without localising features. Typically, there is a leucopenia. Blood culture establishes the diagnosis and multiple cultures increase the yield. Stool cultures are often positive in the second and third weeks. The Widal test detects antibodies to the O and H antigens but is not specific.

#### Management

Antibiotic therapy must be guided by in vitro sensitivity testing. Chloramphenicol (500 mg 4 times daily), ampicillin (750 mg 4 times daily) and co-trimoxazole (2 tablets or IV equivalent twice daily) are losing their effect due to resistance in many areas of the world, especially India and South-east Asia. Fluoroquinolones are the drugs of choice (e.g. ciprofloxacin 500 mg twice daily), if nalidixic acid screening predicts susceptibility, but resistance is common, especially in the Indian subcontinent and also in the UK. Extended-spectrum cephalosporins (ceftazidime and cefotaxime) are useful alternatives but have a slightly increased

treatment failure rate. Azithromycin (500 mg once daily) is an alternative when fluoroquinolone resistance is present but has not been validated in severe disease. Treatment should be continued for 14 days. Pyrexia may persist for up to 5 days after the start of specific therapy. Even with effective chemotherapy, there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers were formerly treated for 4 weeks with ciprofloxacin but may require an alternative agent and duration, as guided by antimicrobial sensitivity testing. Cholecystectomy may be necessary.

**Prevention**

Improved sanitation and living conditions reduce the incidence of typhoid. Travellers to countries where enteric infections are endemic should be inoculated with one of the three available typhoid vaccines (two inactivated injectable and one oral live attenuated).

### Tularaemia

Tularaemia is primarily a zoonotic disease of the northern hemisphere. It is caused by a highly infectious Gram-negative bacillus, *Francisella tularensis*. *F. tularensis* is passed transovarially (ensuring transmission from parent to progeny) in ticks, which allows persistence in nature without the absolute requirement for an infected animal reservoir. It is a potential weapon for bioterrorism. Wild rabbits, rodents and domestic dogs or cats are potential reservoirs, and ticks, mosquitoes or other biting flies are the vectors.

Infection is introduced either through an arthropod or animal bite or via contact with infected animals, soil or water through skin abrasions. The most common ‘ulceroglandular’ variety of the disease (70–80%) is characterised by skin ulceration with regional lymphadenopathy. There is also a purely ‘glandular’ form. Alternatively, inhalation of the infected aerosols may result in pulmonary tularaemia, presenting as pneumonia. Rarely, the portal of entry of infection may be the conjunctiva, leading to a nodular, ulcerated conjunctivitis with regional lymphadenopathy (an ‘oculoglandular’ form). TYPHOIDAL tularaemia is a rare and serious form of tularaemia with vomiting, diarrhoea and hepatosplenomegaly, which may be complicated by pneumonia and meningitis.

**Investigations and management**

Demonstration of a single high titre (≥1 : 160) or a fourfold rise in 2–3 weeks in the tularaemia tube agglutination test confirms the diagnosis. Bacterial yield from the lesions is extremely poor. DNA detection methods to enable rapid diagnosis are in development. Even with effective chemotherapy, there is still a danger of complications, recrudescence of the disease and the development of a carrier state.

Chronic carriers were formerly treated for 4 weeks with ciprofloxacin but may require an alternative agent and duration, as guided by antimicrobial sensitivity testing. Cholecystectomy may be necessary.

### Melioidosis

Melioidosis is caused by *Burkholderia pseudomallei*, a saprophyte found in soil and water (rice paddy fields). Infection is by inoculation or inhalation, leading to bacteraemia, which is followed by the formation of abscesses in the lungs, liver and spleen. Patients with diabetes, renal stones, thalassaemia or severe burns are particularly susceptible. The disease is most common in South-east Asia and northern Australia, and carries a significant mortality. Disease may present years or decades after the initial exposure.

**Clinical features**

Pneumonia is the most common feature but localised skin nodules and abscesses, or sepsis, especially in diabetics, may occur. Diarrhoea and hepatosplenomegaly may be observed. The chest X-ray can resemble cavitatory tuberculosis. In chronic forms, multiple abscesses occur in subcutaneous tissue, liver, spleen and bone, accompanied by profound weight loss.

**Investigations and management**

Culture of blood, sputum or pus on selective media, e.g. Ashdown agar, may yield *B. pseudomallei*. Latex agglutination has been developed as a rapid diagnostic test in Thailand and PCR-based tests are also available. Indirect haemagglutination testing can be helpful in travellers; however, most people in endemic areas are seropositive.

In the acute illness, prompt initiation of empirical therapy is life-saving. Cefazidime 100 mg/kg (2 g 3 times daily) or meropenem (0.5–1 g 3 times daily) is given for 2–3 weeks, followed by maintenance therapy of co-trimoxazole (sulfamethoxazole 1600 mg plus trimethoprim 320 mg twice daily) or doxycycline 200 mg daily for 3–6 months. Abscesses should be drained surgically.

### Actinomycete infections

**Nocardiosis**

Nocardiosis is an uncommon infection caused by aerobic Actinomycetes of the genus *Nocardia*, which are found in the soil. Infection occurs most frequently by direct traumatic inoculation or occasionally via inhalation or ingestion. Nocardiosis can result in localised cutaneous ulcers or nodules, most often in the lower limbs. Chronic destructive infection in tropical countries can result in actinomycetoma, involving soft tissues with occasional penetration to the bone. Actinomycetoma may also be caused by other aerobic Actinomycetes, and a similar clinical syndrome, eumycetoma, is caused by filamentous fungi. Both conditions are discussed on page 301. Systemic *Nocardia* infection, most commonly in immunocompromised individuals, results in suppurative disease with lung and brain abscesses.

On microscopy, *Nocardia* spp. appear as long, filamentous, branching Gram-positive rods, which are also weakly acid-fast. They are easily grown in culture but require prolonged incubation.

Treatment of systemic infection is guided by sensitivity testing and typically requires combinations of imipenem with ceftriaxone, amikacin or co-trimoxazole, often for 6–12 months or longer. Meropenem, tigecycline, linezolid and minocycline may also be used with severe disease or with allergy, or when intolerance prevents use of the preferred agents. Abscesses are drained surgically when this is feasible. Localised cutaneous infection is usually treated with a single agent for 1–3 months. Treatment of actinomycetoma is discussed on page 301.

**Actinomyces spp.**

*Actinomyces* are anaerobic Actinomycetes, which are predominantly commensals of the oral cavity. They are capable of causing deep, suppurating infection in the head and neck (cervicofacial actinomycosis) and the lungs (thoracic actinomycosis). They also cause suppurating disease in the pelvis, associated with intrauterine contraceptive devices (IUCDs). Modern diagnostic techniques demonstrate that actinomycosis...
Gastrointestinal bacterial infections

The approach to patients presenting with acute gastroenteritis is described on page 227.

Staphylococcal food poisoning

Staph. aureus is transmitted via the hands of food handlers to foodstuffs such as dairy products, including cheese, and cooked meats. Inappropriate storage of these foods allows growth of the organism and production of one or more heat-stable enterotoxins that cause the symptoms.

Nausea and profuse vomiting develop within 1–6 hours. Diarrhoea may not be marked. The toxins that cause the syndrome act as ‘super-antigens’ and induce a significant neutrophil leucocytosis that may be clinically misleading. Most cases settle rapidly but severe dehydration can occasionally be life-threatening.

Antiemetics and appropriate fluid replacement are the mainstays of treatment. Suspect food should be cultured for staphylococci and demonstration of toxin production. The public health authorities should be notified if food vending is involved.

Bacillus cereus food poisoning

Ingestion of the pre-formed heat-stable exotoxins of B. cereus causes rapid onset of vomiting and some diarrhoea within hours of food consumption, which resolves within 24 hours. Fried rice and freshly made sauces are frequent sources; the organism grows and produces enterotoxin during storage (Fig. 11.25).

If viable bacteria are ingested and toxin formation takes place within the gut lumen, then the incubation period is longer (12–24 hours) and watery diarrhoea and cramps are the predominant symptoms. The disease is self-limiting but can be quite severe. Rapid and judicious fluid replacement and appropriate notification of the public health authorities are all that is required.

Clostridium perfringens food poisoning

Spores of C. perfringens are widespread in the guts of large animals and in soil. If contaminated meat products are incompletely cooked and stored in anaerobic conditions, C. perfringens spores germinate and viable organisms multiply. Subsequent reheating of the food causes release of enterotoxin. Symptoms (diarrhoea and cramps) occur some 6–12 hours following ingestion. The illness is usually self-limiting.

Clostridial enterotoxins are potent and most people who ingest them will be symptomatic. ‘Point source’ outbreaks, in which a number of cases all become symptomatic following ingestion, classically occur after school or canteen lunches where meat stews are served.

Clostridial necrotising enteritis (CNE) or pigbel is an often-fatal type of food poisoning caused by a β-toxin of C. perfringens, type C. The toxin is normally inactivated by certain proteases or by normal cooking. Pigbel is more likely in protein malnutrition or in the presence of trypsin inhibitors, either in foods such as sweet potatoes or during infection with Ascaris sp. roundworms.

Campylobacter jejuni infection

This infection is essentially a zoonosis, although contaminated water may be implicated, as the organism can survive for many weeks in fresh water. The most common sources of the infection are chicken, beef and contaminated milk products. Pet puppies have also been sources. Campylobacter infection is now the most common cause of bacterial gastroenteritis in the UK, accounting for some 100 000 cases per annum, most of which are sporadic.

The incubation period is 2–5 days. Colicky abdominal pain may be severe and mimic acute appendicitis or other surgical pathology. Nausea, vomiting and significant diarrhoea, frequently containing blood, are common features. The majority of Campylobacter infections affect fit young adults and are self-limiting after 5–7 days. About 10–20% will have prolonged symptomatology, occasionally meriting treatment with a macrolide, most often azithromycin, as many organisms are resistant to ciprofloxacin.

Approximately 1% of cases will develop bacteraemia and possible distant foci of infection. Campylobacter spp. have been linked to Guillain–Barré syndrome and post-infectious reactive arthritis (pp. 1140 and 1031).

Salmonella spp. infection

Salmonella enterica serovars other than Salmonella Typhi and Paratyphi (p. 260), of which there are more than 2000, can cause gastroenteritis. They are widely distributed throughout the animal kingdom. Two serovars are most important worldwide: Salmonella Enteritidis phage type 4 and Salmonella Typhimurium dt.104.

is caused by many different Actinomycetes species, the most common of which is Actinomycetes israelii. Treatment of established disease requires prolonged (about 6–12 months) of penicillin or doxycycline. Early disease may respond to shorter antibiotic courses.

β-toxin of C. perfringens
latter may be resistant to commonly used antibiotics such as ciprofloxacin. Some strains have a clear relationship to particular animal species, e.g. *Salmonella* Arizonae and pet reptiles. Transmission is by contaminated water or food, particularly poultry, egg products and minced beef, direct person-to-person spread or the handling of exotic pets such as salamanders, lizards or turtles. The incidence of *Salmonella* enteritis is falling in the UK due to an aggressive culling policy in broiler chicken stocks, coupled with vaccination.

The incubation period of *Salmonella* gastroenteritis is 12–72 hours and the predominant feature is diarrhoea, sometimes with passage of blood. Vomiting may be present at the outset. Approximately 5% of cases are bacteraemic and invasive non-typhoidal salmonellosis is a leading cause of bacteraemia in sub-Saharan Africa. Reactive (post-infective) arthritis occurs in approximately 2%.

Antibiotics are not indicated for uncomplicated *Salmonella* gastroenteritis but are prescribed for bacteraemia. Salmonellae are notorious for persistent infection and can seed endothelial surfaces such as an atherosclerotic aorta. Mortality, as with other forms of gastroenteritis, is higher in the elderly (see Box 11.12, p. 228).

### Escherichia coli infection

Many serotypes of *E. coli* constitute part of the human gut microbiome. Clinical disease requires either colonisation with a new or previously unrecognized strain, or the acquisition by current colonising bacteria of a particular pathogenicity factor for mucosal attachment or toxin production. Travel to unfamiliar areas can be a contributing factor for new or previously unrecognised strain, or the acquisition by the microbiome. Clinical disease requires either colonisation with virulence factors.

#### Enterotoxigenic *E. coli*

Enterotoxigenic *E. coli* (ETEC) is the most common cause of travellers' diarrhoea, although there are other causes (see Box 11.20, p. 232). The organisms produce either a heat-labile or a heat-stable enterotoxin, causing marked secretory diarrhoea and vomiting after 1–2 days' incubation. The illness is usually mild and self-limiting after 3–4 days. Antibiotics are of questionable value (p. 232).

#### Enteroinvasive *E. coli*

Illness caused by enteroinvasive *E. coli* (EIEC) is very similar to *Shigella* dysentery (p. 265) and is caused by invasion and destruction of colonic mucosal cells. No enterotoxin is produced. Acute watery diarrhoea, abdominal cramps and some scanty blood-staining of the stool are common. The symptoms are rarely severe and are usually self-limiting.

#### Enteropathogenic *E. coli*

Enteropathogenic *E. coli* (EPEC) organisms are very important in infant diarrhoea. They are able to attach to the gut mucosa, inducing a specific ‘attachment and effacement’ lesion and causing destruction of microvilli and disruption of normal absorptive capacity. The symptoms vary from mild non-bloody diarrhoea to quite severe illness, but without bacteraemia.

### Entero-aggregative *E. coli*

Entero-aggregative *E. coli* (EAEC) strains adhere to the mucosa but also produce a locally active enterotoxin and demonstrate a particular ‘stacked brick’ aggregation to tissue culture cells when viewed by microscopy. They have been associated with prolonged diarrhoea in children in South America, South-east Asia and India.

### Enterohaemorrhagic *E. coli*

A number of distinct ‘O’ serotypes of *E. coli* possess both the genes necessary for adherence (see ‘EPEC’ above) and plasmids encoding two distinct enterotoxins (verotoxins), which are identical to the toxins produced by *Shigella* (‘shiga toxins 1 and 2’). *E. coli* O157:H7 is perhaps the best known of these verotoxin-producing *E. coli* (VTEC) but others, including types O126 and O11, are also implicated. In 2011, an outbreak of food-borne illness linked to fenugreek seeds occurred in Germany and was due to *E. coli* O104:H4, an EAEC strain that had acquired genes encoding shiga toxin 2a. Although the incidence of enterohaemorrhagic *E. coli* (EHEC) is considerably lower than that of *Campylobacter* and *Salmonella* infection, it is increasing in the developing world.

The reservoir of infection is in the gut of herbivores. The organism has an extremely low infecting dose (10–100 organisms). Runoff water from pasture lands where cattle have grazed, which is used to irrigate vegetable crops, as well as contaminated milk, meat products (especially hamburgers that have been incompletely cooked), lettuce, radish shoots and apple juice have all been implicated as sources (Fig. 11.26).

The incubation period is between 1 and 7 days. Initial watery diarrhoea becomes uniformly blood-stained in 70% of cases and...
is associated with severe abdominal pain. There is little systemic upset, vomiting or fever.

Enterotoxins have both a local effect on the bowel and a distant effect on particular body tissues, such as glomerular apparatus, heart and brain. The potentially life-threatening haemolytic uraemic syndrome (HUS, p. 408) occurs in 10–15% of sufferers from this infection, arising 5–7 days after the onset of symptoms. It is most likely at the extremes of age, is heralded by a high peripheral leucocyte count, and may be induced, particularly in children, by antibiotic therapy.

HUS is treated by dialysis if necessary and may be averted by plasma exchange. Antibiotics should be avoided since they can stimulate toxin release.

**Clostridium difficile infection**

*C. difficile* is the most commonly diagnosed cause of antibiotic-associated diarrhoea (p. 230), and is an occasional constituent of the gut microbiome. *C. difficile* can produce two toxins (A and B). *C. difficile* infection (CDI) usually follows antimicrobial therapy, which alters the composition of the gastrointestinal flora and may result in colonisation with toxigenic *C. difficile*, if the patient is exposed to *C. difficile* spores. The combination of toxin production and the ability to produce environmentally stable spores accounts for the clinical features and transmissibility of CDI. A hypervirulent strain of *C. difficile*, ribotype 027, has emerged, which produces more toxin and more severe disease than other *C. difficile* strains.

**Clinical features**

Disease manifestations range from diarrhoea to life-threatening pseudomembranous colitis. Around 80% of cases occur in people over 65 years of age, many of whom are frail with comorbid diseases. Symptoms usually begin in the first week of antibiotic therapy but can occur at any time up to 6 weeks after treatment has finished. The onset is often insidious, with lower abdominal pain and diarrhoea that may become profuse and watery. The presentation may resemble acute ulcerative colitis with bloody diarrhoea, fever and even toxic dilatation and perforation. Ileus is also seen in pseudomembranous colitis.

**Investigations**

*C. difficile* can be isolated from stool culture in 30% of patients with antibiotic-associated diarrhoea and over 90% of those with pseudomembranous colitis, but also from 5% of healthy adults and up to 20% of elderly patients in residential care. The diagnosis of CDI therefore rests on detection of toxins A or B in the stool. Current practice in the UK is to screen stools from patients with a compatible clinical syndrome by detection either of glutamate dehydrogenase (GDH), an enzyme produced by *C. difficile*, or of *C. difficile* nucleic acid (e.g. by PCR); if screening is positive, a *C. difficile* toxin ELISA or a tissue culture cytotoxicity assay is performed.

The rectal appearances at sigmoidoscopy may be characteristic, with erythema, white plaques or an adherent pseudomembrane (Fig. 11.27), or may resemble ulcerative colitis. In some cases, the rectum is spared and abnormalities are observed in the proximal colon. Patients who are ill require abdominal and erect chest X-rays to exclude perforation or toxic dilatation. CT may be useful when the diagnosis is in doubt.

**Management**

The precipitating antibiotic should be stopped and the patient should be isolated. Supportive therapy includes intravenous fluids and bowel rest. First-line antimicrobial therapy involves metronidazole (500 mg orally 3 times daily for 10 days) or vancomycin (125 mg orally 4 times daily for 7–10 days). Although vancomycin is more effective than metronidazole against hypervirulent *C. difficile* strains (e.g. ribotype 027), it is more expensive and may drive the emergence of vancomycin resistance in other organisms (e.g. enterococci, *Staph. aureus*). For these reasons, some authorities reserve its use for relapse (15–30% of patients), failure of initial response or severe infection. Fidaxomicin is associated with a lower relapse rate than vancomycin but is more expensive. Intravenous immunoglobulin and/or glucocorticoids are sometimes given in the most severe or refractory cases, and faecal transplantation from a healthy donor is increasingly used to manage relapses by restoring a more advantageous gut microbiome profile. Surgical intervention needs to be considered early in severe cases.

**Yersinia enterocolitica infection**

*Yersinia enterocolitica*, commonly found in pork, causes mild to moderate gastroenteritis and can produce significant mesenteric adenitis after an incubation period of 3–7 days. It predominantly causes disease in children but adults may also be affected. The illness resolves slowly. Complications include reactive arthritis (p. 1031; 10–13% of cases), which may be persistent, and anterior uveitis.

**Cholera**

Cholera, caused by *Vibrio cholerae* serotype O1, is the archetypal toxin-mediated bacterial cause of acute watery diarrhoea. The enterotoxin activates adenylyl cyclase in the intestinal epithelium, inducing net secretion of chloride and water. *V. cholerae* O1 has two biotypes, classical and El Tor, and each of these has two distinct serotypes, Inaba and Ogawa. Following its origin in the Ganges valley, devastating epidemics have occurred, often in association with large religious festivals, and pandemics have spread worldwide. The seventh pandemic, due to the El Tor biotype, began in 1961 and spread via the Middle East to become endemic in Africa, subsequently spreading throughout South and Central America. Numbers of cases of cholera have been increasing, with outbreaks in Ghana in 2014 and Tanzania in 2015. El Tor is more resistant to commonly used antimicrobials than classical *Vibrio*, and causes prolonged carriage in 5% of
infections. An atypical serotype, O139, has been responsible for localised outbreaks in Bangladesh.

Infection spreads via the stools or vomit of symptomatic patients or of the much larger number of subclinical cases. Organisms survive for up to 2 weeks in fresh water and 8 weeks in salt water. Transmission is normally through infected drinking water, shellfish and food contaminated by flies, or on the hands of carriers.

**Clinical features**

Severe diarrhoea without pain or colic begins suddenly and is followed by vomiting. Following the evacuation of normal gut faecal contents, typical ‘rice water’ material is passed, consisting of clear fluid with flecks of mucus. Classical cholera produces enormous loss of fluid and electrolytes, leading to intense dehydration with muscular cramps. Shock and oliguria develop but mental clarity remains. Death from acute circulatory failure may occur rapidly unless fluid and electrolytes are replaced. Improvement is rapid with proper treatment.

The majority of infections, however, cause mild illness with slight diarrhoea. Occasionally, a very intense illness, ‘cholera sicca’, occurs, with loss of fluid into dilated bowel, killing the patient before typical gastrointestinal symptoms appear. The disease is more dangerous in children.

**Diagnosis and management**

Clinical diagnosis is easy during an epidemic. Otherwise, the diagnosis should be confirmed bacteriologically. Stool dark-field microscopy shows the typical ‘shooting star’ motility of *V. cholerae*. Rectal swab or stool cultures allow identification. Cholera is notifiable under international health regulations.

Maintenance of circulation by replacement of water and electrolytes is paramount (p. 229). Ringer-Lactate is the best fluid for intravenous replacement. Vomiting usually stops once the patient is rehydrated, and fluid should then be given orally up to 500 mL hourly. Early intervention with oral rehydration solutions that include resistant starch, based on either rice or cereal, shortens the duration of diarrhoea and improves prognosis.

Severe dehydration, as indicated by altered consciousness, skin tenting, very dry tongue, decreased pulses, low blood pressure, and mental confusion, mandates intravenous replacement. Total fluid requirements may exceed 50 L over a period of 2–5 days. Accurate records are greatly facilitated by the use of a ‘cholera cot’, which has a reinforced hole under the patient’s buttocks, beneath which a graded bucket is placed.

Three-day treatment with tetracycline 250 mg 4 times daily, a single dose of doxycycline 300 mg or ciprofloxacin 1 g in adults reduces the duration of excretion of *V. cholerae* and the total volume of fluid needed for replacement.

**Prevention**

Strict personal hygiene is vital and drinking water should come from a clean piped supply or be boiled. Flies must be denied access to food. Oral vaccines containing killed *V. cholerae* with or without the B subunit of cholera toxin are used in specific settings.

In epidemics, improvements in sanitation and access to clean water, public education and control of population movement are vital. Mass single-dose vaccination and treatment with tetracycline are valuable. Disinfection of discharges and soiled clothing, and scrupulous hand-washing by medical attendants reduce spread.

**Vibrio parahaemolyticus infection**

This marine organism produces a disease similar to entero-toxic *E. coli* (see above). It is very common where ingestion of raw seafood is widespread (e.g. Japan). After an incubation period of approximately 20 hours, explosive diarrhoea, abdominal cramps and vomiting occur. Systemic symptoms of headache and fever are frequent but the illness is self-limiting after 4–7 days. Rarely, a severe septic illness arises; in this case, *V. parahaemolyticus* can be isolated using specific halophilic culture.

**Bacillary dysentery (shigellosis)**

Shigellosis are Gram-negative rods, closely related to *E. coli*, that invade the colonic mucosa. There are four main groups: *Sh. dysenteriae*, *flexneri*, *boydii* and *sonnei*. In the tropics, bacillary dysentery is usually caused by *Sh. flexneri*, while in the UK most cases are caused by *Sh. sonnei*. Shigellosis are often resistant to multiple antibiotics, especially in tropical countries. The organism only infects humans and its spread is facilitated by its low infecting dose of around 10 organisms.

Spread may occur via contaminated food or flies, but person-to-person transmission by unwashed hands after defaecation is the most important factor. Outbreaks occur in psychiatric hospitals, residential schools and other closed institutions, and dysentery is a constant accompaniment of wars and natural catastrophes, which bring crowding and poor sanitation in their wake. Shigella infection may spread rapidly among men who have sex with men.

**Clinical features**

Disease severity varies from mild *Sh. sonnei* infections that may escape detection to more severe *Sh. flexneri* infections, while those due to *Sh. dysenteriae* may be fulminating and cause death within 48 hours.

In a moderately severe illness, the patient complains of diarrhoea, colicky abdominal pain and tenesmus. Stools are small, and after a few evacuations contain blood and purulent exudate with little faecal material. Fever, dehydration and weakness occur, with tenderness over the colon. Reactive arthritis or iritis may occasionally complicate bacillary dysentery (p. 1031).

**Management and prevention**

Oral rehydration therapy or, if diarrhoea is severe, intravenous replacement of water and electrolyte loss is necessary. Antibiotic therapy is with ciprofloxacin (500 mg twice daily for 3 days) or ceftriaxone. Azithromycin and ceftriaxone are alternatives but resistance occurs to all agents, especially in Asia. The use of antidiarrhoeal medication should be avoided.

The prevention of faecal contamination of food and milk and the isolation of cases may be difficult, except in limited outbreaks. Hand-washing is very important.

**Respiratory bacterial infections**

Most of these infections are described in Chapter 17.

**Diphtheria**

Infection with Corynebacterium diphtheriae occurs most commonly in the upper respiratory tract and is usually spread by droplet infection. Infection may also complicate skin lesions, especially in alcoholics. The organisms remain localised at the site of infection but release of a soluble exotoxin damages the heart muscle and the nervous system.

Diphtheria has been eradicated from many parts of the world by mass vaccination using a modified exotoxin but remains
important in areas where vaccination has been incomplete, e.g. in Russia and South-east Asia. The disease is notifiable in all countries of Europe and North America, and international guidelines have been issued by the WHO for the management of infection.

**Clinical features**

The average incubation period is 2–4 days. The disease begins insidiously with a sore throat (Box 11.44). Despite modest fever, there is usually marked tachycardia. The diagnostic feature is the ‘wash-leather’ elevated, greyish-green membrane on the tonsils. It has a well-defined edge, is firm and adherent, and is surrounded by a zone of inflammation. There may be swelling of the neck (‘bull neck’) and tender enlargement of the lymph nodes. In the mildest infections, especially where there is a high degree of immunity, a membrane may not appear and inflammation is minimal.

With anterior nasal infection there is nasal discharge, frequently blood-stained. In laryngeal diphtheria, a husky voice and high-pitched cough signal potential respiratory obstruction requiring urgent tracheostomy. If infection spreads to the uvula, fauces and nasopharynx, the patient is gravely ill.

Death from acute circulatory failure may occur within the first 10 days. Late complications arise as a result of toxin action on the heart or nervous system. About 25% of survivors of the early toxaemia may later develop myocarditis with arrhythmias or cardiac failure. These are usually reversible, with no permanent damage other than heart block in survivors.

Neurological involvement occurs in 75% of cases. After tonsillar or pharyngeal diphtheria, it usually starts after 10 days with palatal palsy. Paralysis of accommodation often follows, manifest by difficulty in reading small print. Generalised polyneuritis with weakness and paraesthesia may follow in the next 10–14 days. Recovery from such neuritis is always ultimately complete.

**Management**

A clinical diagnosis of diphtheria must be notified to the public health authorities and the patient sent urgently to a specialist infectious diseases unit. Empirical treatment should commence after collection of appropriate swabs.

Diphtheria antitoxin is produced from hyperimmune horse serum. It neutralises circulating toxin but has no effect on toxin already fixed to tissues, so it must be injected intramuscularly without awaiting the result of a throat swab. However, reactions to this foreign protein include a potentially lethal immediate anaphylactic reaction (p. 75) and a ‘serum sickness’ with fever, urticaria and joint pains, which occurs 7–12 days after injection. A careful history of previous horse serum injections or allergic reactions should be taken and a small test injection of serum should be given half an hour before the full dose in every patient. Adrenaline (epinephrine) solution must be available to deal with any immediate type of reaction (0.5–1.0 mL of 1/1000 solution IM). An antihistamine is also given. In a severely ill patient, the risk of anaphylactic shock is outweighed by the mortal danger of diphtheritic toxaemia. A dose of up to 100,000 IU of antitoxin is injected intravenously if the test dose is tolerated. For disease of moderate severity, 16,000–40,000 IU IM will suffice, and for mild cases 4000–8000 IU.

Penicillin (1200 mg 4 times daily IV) or amoxicillin (500 mg 3 times daily) should be administered for 2 weeks to eliminate C. diphtheriae. Patients allergic to penicillin can be given erythromycin. Due to poor immunogenicity of primary infection, all sufferers should be immunised with diphtheria toxoid following recovery. Patients must be managed in strict isolation and attended by staff with a clearly documented immunisation history until three swabs 24 hours apart are culture-negative.

**Prevention**

Active immunisation should be given to all children. If diphtheria occurs in a closed community, contacts should be given erythromycin, which is more effective than penicillin in eradicating the organism in carriers.

All contacts should also be immunised or given a booster dose of toxoid. Booster doses are required every 10 years to maintain immunity.

**Pneumococcal infection**

Strep. pneumoniae (the pneumococcus) is the leading cause of community-acquired pneumonia globally (p. 582) and one of the leading causes of infection-related mortality. Otitis media, meningitis and sinusitis are also frequently caused by Strep. pneumoniae. Occasional patients present with bacteremia without obvious focus. Asplenic individuals are at risk of fulminating pneumococcal disease with purpuric rash.

Increasing rates of penicillin resistance have been reported around the world for Strep. pneumoniae, although they remain low in the UK. Strains with cephalosporin resistance causing meningitis require treatment with a combination of cephalosporins, glycopeptides and rifampicin. Macrolide resistance is also increasing. Newer quinolones are also used (e.g. levofloxacin) but rates of resistance are rising.

Vaccination of infants with the protein conjugate pneumococcal vaccine decreases Strep. pneumoniae infection in infants and in their relatives. The polysaccharide pneumococcal vaccine is used in individuals predisposed to Strep. pneumoniae infection and the elderly, but only modestly reduces pneumococcal bacteraemia and does not prevent pneumonia. All asplenic individuals should receive vaccination against Strep. pneumoniae.

**Anthrax**

Anthrax is an endemic zoonosis in many countries; it causes human disease following inoculation of the spores of Bacillus anthracis. B. anthracis was the first bacterial pathogen described by Koch and the model pathogen for ‘Koch’s postulates’ (see Box 6.1, p. 100). It is a Gram-positive organism with a central spore. The spores can survive for years in soil. Infection is commonly acquired from contact with animals, particularly herbivores. The ease of production of B. anthracis spores makes this infection a candidate for biological warfare or bioterrorism. B. anthracis produces a number of toxins that mediate the clinical features of disease.
Clinical features

These depend on the route of entry of the anthrax spores.

Cutaneous anthrax

This skin lesion is associated with occupational exposure to anthrax spores during processing of hides and bone products. It accounts for the vast majority of clinical cases. Animal infection is a serious problem in Africa, India, Pakistan and the Middle East.

Spores are inoculated into exposed skin. A single lesion develops as an irritable papule on an oedematous haemorrhagic base. This progresses to a depressed black eschar. Despite extensive oedema, pain is infrequent.

Gastrointestinal anthrax

This is associated with the ingestion of contaminated meat. The caecum becomes infected, which produces nausea, vomiting, anorexia and fever, followed in 2–3 days by severe abdominal pain and bloody diarrhoea. Toxaemia and death can develop rapidly thereafter.

Inhalational anthrax

This form of the disease is extremely rare but has been associated with bioterrorism. Without rapid and aggressive therapy at the onset of symptoms, the mortality is 50–90%. Fever, dyspnoea, cough, headache and sepsis develop 3–14 days following exposure. Typically, the chest X-ray shows only widening of the mediastinum and pleural effusions, which are haemorrhagic. Meningitis may occur.

Management

*B. anthracis* can be cultured from skin swabs from lesions. Skin lesions are readily curable with early antibiotic therapy. Treatment is with ciprofloxacin (500 mg twice daily) until penicillin susceptibility is confirmed; the regimen can then be changed to benzylpenicillin with doses up to 2.4 g IV given 6 times daily or phenoxymethylpenicillin 500–1000 mg 4 times daily administered for 10 days. The addition of an aminoglycoside may improve the outlook in severe disease. In view of concerns about concomitant inhalational exposure, particularly in the era of bioterrorism, a further 2-month course of ciprofloxacin 500 mg twice daily or doxycycline 100 mg twice daily orally is added to eradicate inhaled spores. Inhalational anthrax is treated with ciprofloxacin and clindamycin for at least 14 days, followed by therapy to eradicate spores. Monoclonal antibodies against *B. anthracis* protective antigen can be added for systemic infection. Prophylaxis with ciprofloxacin (500 mg twice daily for 2 months) is recommended for anyone at high risk of inhalational exposure to anthrax spores and should be combined with three doses of anthrax vaccine adsorbed (AVA).

Bacterial infections with neurological involvement

Infections affecting the CNS, including bacterial meningitis, botulism and tetanus, are described on page 1117.

Mycobacterial infections

Tuberculosis

Tuberculosis is predominantly, although by no means exclusively, a respiratory disease and is described on page 588.

Leprosy

Leprosy (Hansen’s disease) is a chronic granulomatous disease affecting skin and nerves and caused by *Mycobacterium leprae*, a slow-growing mycobacterium that cannot be cultured in vitro. The clinical manifestations are determined by the degree of the patient’s cell-mediated immunity (CMI) (p. 69) towards *M. leprae* (Fig. 11.28). High levels of CMI with elimination of leprosy bacilli produces tuberculous leprosy, whereas absent CMI results in lepromatous leprosy. Complications arise due to nerve damage, immunological reactions and bacillary infiltration. People with leprosy are frequently stigmatised and using the word ‘leper’ is inappropriate.

Epidemiology and transmission

Some 4 million people have leprosy and around 750,000 new cases are detected annually. About 70% of the world’s leprosy patients live in India, with the disease endemic in Brazil, Indonesia, Mozambique, Madagascar, Tanzania and Nepal.

Untreated lepromatous patients discharge bacilli from the nose. Infection occurs through the nose, followed by haematogenous spread to skin and nerve. The incubation period is 2–5 years for tuberculous cases and 8–12 years for lepromatous cases. Leprosy incidence peaks at 10–14 years, and is more common in males and in household contacts of leprosy cases.

Pathogenesis

*M. leprae* has tropism for Schwann cells and skin macrophages. In tuberculoid leprosy, effective CMI controls bacillary multiplication (‘paucibacillary’) and organised epithelioid granulomata form. In lepromatous leprosy, there is abundant bacillary multiplication (‘multibacillary’), e.g. in Schwann cells and perineurium. Between these two extremes is a continuum, varying from patients with...
moderate CMI (borderline tuberculoid) to patients with little cellular response (borderline lepromatous).

Immuno logical reactions evolve as the immune response develops and the bacillary antigenic stimulus varies, particularly in borderline patients. Delayed hypersensitivity reactions produce type 1 (reversal) reactions, while immune complexes contribute to type 2 (erythema nodosum leprosum) reactions.

HIV/leprosy co-infected patients have typical lepromatous and tuberculoid leprosy skin lesions and typical leprosy histology and granuloma formation. Surprisingly, even with low circulating CD4 counts, tuberculoid leprosy may be observed and there is not an obvious shift to lepromatous leprosy.

**Clinical features**

Box 11.45 gives the cardinal features of leprosy. Types of leprosy are compared in Box 11.46.

- **Skin.** The most common skin lesions are macules or plaques. Tuberculoid patients have few, hypopigmented lesions (Fig. 11.29A). In lepromatous leprosy, papules, nodules or diffuse infiltration of the skin occur. The earliest lesions are ill defined; gradually, the skin becomes infiltrated and thickened. Facial skin thickening leads to the characteristic leonine facies (Fig. 11.29B).

...are obtained by scraping dermal material on to a glass slide. The smears are then stained for acid-fast bacilli, the number counted per high-power field and a score derived on a logarithmic scale (0–6): the bacterial index (BI). Smears are useful for confirming the diagnosis and monitoring response to treatment. Neither serology nor PCR is sensitive or specific enough for diagnosis.

Management

The principles of treatment are outlined in Box 11.48. All leprosy patients require MDT with an approved first-line regimen (Box 11.49).

Rifampicin is a potent bactericidal for *M. leprae* but should always be given in combination with other antileptotics, since a single-step mutation can confer resistance. Dapsone is bacteriostatic. It commonly causes mild haemolysis and rarely anaemia. Clofazimine is a red, fat-soluble crystalline dye, weakly bactericidal for *M. leprae*. Skin discoloration (red to purple–black) and ichthyosis are troublesome side-effects, particularly on pale skins. New bactericidal drugs against *M. leprae* have been identified, notably fluoroquinolones (pefloxacin and ofloxacin). Minocycline and clarithromycin may also be used. These agents are now established second-line drugs. Minocycline causes a grey pigmentation of skin lesions.

ereumatous (Fig. 11.29D). Peripheral nerves become tender and painful, with sudden loss of nerve function. These reactions may occur spontaneously, after starting treatment and also after completion of multidrug therapy (MDT).

- Type 2 (erythema nodosum leprosum, ENL) reactions. These are partly due to immune complex deposition and occur in BL and LL patients who produce antibodies and have a high antigen load. They manifest with malaise, fever and crops of small pink nodules on the face and limbs. Iritis and episcleritis are common. Other signs are acute neuritis, lymphadenitis, orchitis, bone pain, dactylitis, arthritis and proteinuria. ENL may continue intermittently for several years.

Borderline cases

In borderline tuberculoid (BT) cases, skin lesions are more numerous than in tuberculoid (TT) cases, and there is more severe nerve damage and a risk of type 1 reactions. In borderline lepromatous (BB) cases, skin lesions are widespread and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. In borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. Reversal (type 1) reactions. Erythematous, oedematous lesions.

**Fig. 11.29 Clinical features of leprosy.**

A Tuberculoid leprosy. Single lesion with a well-defined active edge and anaesthesia within the lesion. B Lepromatous leprosy. Widespread nodules and infiltration, with loss of the eyebrows. This man also has early collapse of the nose. C Borderline tuberculoid leprosy with severe nerve damage. This boy has several well-defined, hypopigmented, macular, anaesthetic lesions. He has severe nerve damage affecting both ulnar and median nerves bilaterally and has sustained severe burns to his hands. D Reversal (type 1) reactions. Erythematous, oedematous lesions.

**Investigations**

The diagnosis is clinical, made by finding a cardinal sign of leprosy and supported by detecting acid-fast bacilli in slit-skin smears or typical histology in a skin biopsy. Slit-skin smears
Although single-dose treatment is less effective than the conventional 6-month treatment for paucibacillary leprosy, it is an operationally attractive field regimen recommended by the WHO.

Leprosy reactions are treated as shown in Box 11.47. Chloroquine can also be used.

**Patient education**

This is essential and should patients should be informed that, after 3 days of chemotherapy, they are not infectious and can lead a normal social life. It should emphasise that gross deformities are not inevitable.

Patients with anaesthetic hands or feet need to avoid and treat burns or other minor injuries. Good footwear is important. Physiotherapy helps maintain range of movement of affected muscles and neighbouring joints.

**Prognosis**

Untreated, tuberculous leprosy has a good prognosis; it may self-heal and peripheral nerve damage is limited. Lepromatous leprosy (LL) is a progressive condition with high morbidity if untreated.

After treatment, the majority of patients, especially those who have no nerve damage at the time of diagnosis, do well, with resolution of skin lesions. Borderline patients are at risk of developing type 1 reactions, which may result in devastating nerve damage.

**Prevention and control**

The previous strategy of centralised leprosy control campaigns has been superseded by integrated programmes, with primary health-care workers in many countries now responsible for case detection and provision of MDT. It is not yet clear how successful this will be, especially in the time-consuming area of disability prevention.

BCG vaccination has been shown to give good but variable protection against leprosy; adding killed *M. leprae* to BCG does not enhance protection.

### Rickettsial and related intracellular bacterial infections

#### Rickettsial fevers

The rickettsial fevers are the most common tick-borne infections. It is important to ask potentially infected patients about contact with ticks, lice or fleas. There are two main groups of rickettsial fevers: spotted fevers and typhus (Box 11.50).

**Pathogenesis**

The rickettsiae are intracellular Gram-negative organisms that parasitise the intestinal canal of arthropods. Infection of humans through the skin occurs from the excreta of arthropods, but the saliva of some biting vectors is infected. The organisms multiply in capillary endothelial cells, producing lesions in the skin, CNS, heart, lungs, liver, kidneys and skeletal muscles. Endothelial proliferation, associated with a perivascular reaction, may cause thrombosis and purpura. In epidemic typhus, the brain is the target organ; in scrub typhus, the cardiovascular system and lungs in particular are attacked. An eschar, a black necrotic crusted sore, is often found in tick- and mite-borne typhus (see Fig. 11.7C, p. 235). This is due to vasculitis following immunological recognition of the inoculated organism. Regional lymph nodes often enlarge.

**Spotted fever group**

**Rocky Mountain spotted fever**

*Rickettsia rickettsii* is transmitted by tick bites. It is widely distributed and increasing in western and south-eastern states of the USA and also in Central and South America. The incubation period is about 7 days. The rash appears on about the third or fourth day of illness, looking at first like measles, but in a few hours a typical maculopapular eruption develops. The rash spreads in 24–48 hours from wrists, forearms and ankles to the back, limbs and chest, and then to the abdomen, where it is least pronounced. Larger cutaneous and subcutaneous haemorrhages may appear in severe cases. The liver and spleen become palpable. At the extremes of life, the mortality is 2–12%.

**Other spotted fevers**

*R. conorii* (boutonneuse fever) and *R. africae* (African tick bite fever) cause Mediterranean and African tick typhus, which also occurs on the Indian subcontinent. The incubation period is approximately 7 days. Infected ticks may be picked up by walking on grasslands, or dogs may bring ticks into the house. Careful examination might reveal a diagnostic eschar, and the maculopapular rash on the trunk, limbs, palms and soles. There may be delirium and meningeal signs in severe infections but recovery is usual. *R. africae* can be associated with multiple eschars. Some cases, particularly those with *R. africae*, present without rash (“spotless spotted fever’). Other spotted fevers are shown in Box 11.50.

**Typhus group**

**Scrub typhus fever**

Scrub typhus is caused by *Orientia tsutsugamushi* (formerly *Rickettsia tsutsugamushi*), transmitted by mites. It occurs in the Far East, Myanmar, Pakistan, Bangladesh, India, Indonesia, the South Pacific islands and Queensland, particularly where patches of forest cleared for plantations have attracted rats and mites.

In many patients, one eschar or more develops, surrounded by an area of cellulitis (see Fig. 11.7C, p. 235) and
Epidemic typhus is caused by Orientia tsutsugamushi, which is transmitted by infected ticks. The incubation period is usually 10–14 days. The onset of symptoms is often sudden, with headache (often retro-orbital), fever, malaise, weakness, and cough. In severe illness, the general symptoms increase, with apathy and prostration. An erythematous maculopapular rash often appears on about the 5th–7th day and spreads to the trunk, face, and limbs, including the palms and soles, with generalised painless lymphadenopathy. The rash fades by the 14th day. The temperature rises rapidly and continues to rise by the 18th day. Convalescence is often slow and tachycardia may persist for some weeks.

Endemic (flea-borne) typhus

Endemic typhus is caused by R. prowazekii and is transmitted by infected fleas of the human body louse. The incubation period is usually 12–14 days. There may be a few days of malaise but the onset is more often sudden, with rigor, fever, frontal headaches, pains in the back and limbs, constipation and bronchitis. The face is flushed and cyanotic, the eyes are congested and the patient becomes confused. The rash appears on the 4th–6th day. In its early stages, it disappears on pressure but soon becomes petechial with subcutaneous mottling. It appears first on the anterior folds of the axilla, sides of the abdomen or backs of hands, then on the trunk and forearms. The neck and face are seldom affected. Cardiac failure, renal failure and haemorrhage may develop. Convalescence is often slow and tachycardia may persist for weeks.

Investigation of rickettsial infection

Routine blood investigations are not diagnostic. There is usually hepatosplenomegaly, and thrombocytopenia. Diagnosis is made on clinical grounds and response to treatment, and may be confirmed by antibody detection or PCR in specialised laboratories. Differential diagnoses include malaria, which should be excluded, typhoid, meningococcal sepsis, and leptospirosis.

Management of rickettsial fevers

The different rickettsial fevers vary in severity but all respond to tetracycline 500 mg 4 times daily, doxycycline 200 mg daily.
or chloramphenicol 500 mg 4 times daily for 7 days. Louseborne typhus and scrub typhus can be treated with a single dose of 200 mg doxycycline, repeated for 2–3 days to prevent relapse. Chloramphenicol- and doxycycline-resistant strains of O. tsutsugamushi have been reported from Thailand and patients here may need treatment with rifampicin.

Nursing care is important, especially in epidemic typhus. Sedation may be required for delirium and blood transfusion for haemorrhage. Relapsing fever and typhoid are common intercurrent infections in epidemic typhus, and pneumonia in scrub typhus, which require diagnosis and treatment. Convalescence is usually protracted, especially in older people.

To prevent rickettsial infection, lice, fleas, ticks and mites need to be controlled with insecticides.

### Q fever

Q fever occurs worldwide and is caused by the rickettsia-like organism Coxiella burnetii, an obligate intracellular organism that survives in the extracellular environment. Cattle, sheep and goats are important reservoirs and the organism is transmitted by inhalation of aerosolised particles. An important characteristic of C. burnetii is its antigenic variation, called phase variation, due to a change of lipopolysaccharide (LPS). When isolated from animals or humans, C. burnetii expresses phase I antigen and is very infectious (a single bacterium is sufficient to infect a human). In culture, there is an antigenic shift to the phase II form, which is not infectious. Measurement of antigenic shift helps differentiate acute and chronic Q fever.

**Clinical features**

The incubation period is 3–4 weeks. The initial symptoms are non-specific with fever, headache and chills; in 20% of cases, a maculopapular rash occurs. Other presentations include pneumonia and hepatitis. Chronic Q fever may present with osteomyelitis, encephalitis and endocarditis.

**Investigations and management**

Diagnosis is usually serological and the stage of the infection can be distinguished by isotype tests and phase-specific antigens. Phase I and II IgM titres peak at 4–6 weeks. In chronic infections, IgG titres to phase I and II antigens may be raised. Prompt treatment of acute Q fever with doxycycline reduces fever duration. Treatment of Q fever endocarditis is problematic, requiring prolonged therapy with doxycycline and rifampicin or ciprofloxacin with hydroxychloroquine; even then, organisms are not always eradicated. Valve surgery is often required (p. 526).

### Bartonellosis

This group of diseases is caused by intracellular Gram-negative bacilli closely related to the rickettsiae, which have been discovered to be important causes of ‘culture-negative’ endocarditis. They are found in many domestic pets, such as cats, although for several the host is undefined (Box 11.51). The principal human pathogens are Bartonella quintana, B. henselae and B. bacilliformis. Bartonella infections are associated with the following:

- **Trench fever.** This is a relapsing fever with severe leg pain and is caused by B. quintana. The disease is not fatal but is very debilitating.

- **Bacteraemia and endocarditis in the homeless.** Endocarditis due to B. quintana or B. henselae is associated with severe damage to the heart valves.

**Clinical diseases caused by Bartonella spp.**

</tr>
</tbody>
</table>

- **Cat scratch disease.** B. henselae causes this common benign lymphadenopathy in children and young adults. A vesicle or papule develops on the head, neck or arms after a cat scratch. The lesion resolves spontaneously but there may be regional lymphadenopathy that persists for up to 4 months before also resolving spontaneously. Rare complications include retinitis and encephalopathy.

- **Bacillary angiomatosis.** This is an HIV-associated disease caused by B. quintana or B. henselae (p. 316).

- **Oroya fever and verruga peruana (Carrion’s disease).** This is endemic in areas of Peru. It is a biphasic disease caused by B. bacilliformis, transmitted by sandflies of the genus Phlebotomus. Fever, haemolytic anaemia and microvascular thrombosis with end-organ ischaemia are features. It is frequently fatal if untreated.

**Investigations and management**

Bartonellae can be cultured in specialised laboratories but PCR is often used to diagnose infection. Serum antibody detection is possible but cross-reactions occur with Chlamydia and Coxiella spp.

**Bartonella** spp. are typically treated with macrolides or tetracyclines. Antibiotic use is guided by clinical need. Cat scratch disease usually resolves spontaneously but Bartonella endocarditis requires valve replacement and combination antibiotic therapy with doxycycline and gentamicin.

### Chlamydial infections

These are listed in Box 11.52 and are also described on pages 340 and 582.
Protozoal infections

Protozoa are responsible for many important infectious diseases. They can be categorised according to whether they cause systemic or local infection. Trichomoniasis is described on page 335.

Systemic protozoal infections

Malaria

Malaria in humans is caused by Plasmodium falciparum, P. vivax, P. ovale (subspecies curtisi and wallikeri), P. malariae and the predominantly simian parasite P. knowlesi. It is transmitted by the bite of female anopheline mosquitoes and occurs throughout the tropics and subtropics at altitudes below 1500 metres (Fig. 11.31). The WHO estimates that 214 million cases of clinical malaria occurred in 2015, 88% of these in Africa, especially among children and pregnant women. WHO prevention and treatment campaigns reduced the incidence of malaria between 1950 and 1960, but since 1970 there has been resurgence. Furthermore, P. falciparum has now become resistant to chloroquine and sulfadoxine-pyrimethamine, initially in South-east Asia and now throughout Africa. The WHO’s Millennium Development Goal malaria target aimed to halt the spread of the disease by 2015 and this has been achieved. The ‘Roll Back Malaria’ campaign was designed to halve mortality by 2010 by utilising the ‘best evidence’ vector and disease control methods, such as artemisinin combination therapy (ACT).

Travellers are susceptible to malaria (p. 230). Most cases are due to P. falciparum, usually from Africa, and of these 1% die because of late diagnosis. Migrants from endemic countries who spend long periods of time in non-endemic countries are particularly at risk if they visit friends and family in their country of origin. They have lost their partial immunity and frequently do not take malaria prophylaxis. A few people living near airports in Europe have acquired malaria from accidentally imported mosquitoes.

Pathogenesis

Life cycle of the malarial parasite

The female anopheline mosquito becomes infected when it feeds on human blood containing gametocytes, the sexual forms of the malarial parasite (Figs 11.32 and 11.33). Development in the mosquito takes 7–20 days, and results in sporozoites accumulating in the salivary glands and being inoculated into the human bloodstream. Sporozoites disappear from human blood within half an hour and enter the liver. After some days, merozoites leave the liver and invade red blood cells, where further asexual cycles of multiplication take place, producing schizonts.

Trachoma

Trachoma is a chronic keratoconjunctivitis caused by Chlamydia trachomatis and is the most common cause of avoidable blindness. The classic trachoma environment is dry and dirty, causing children to have eye and nose discharges. Transmission occurs through flies, on fingers and within families. In endemic areas, the disease is most common in children.

Pathology and clinical features

The onset is usually insidious. Infection may be asymptomatic, lasts for years, may be latent over long periods and may recrudesce. The conjunctiva of the upper lid is first affected with vascularisation and cellular infiltration. Early symptoms include conjunctival irritation and blepharospasm. The early follicles are characteristic (Fig. 11.30) but clinical differentiation from conjunctivitis due to other causes may be difficult. Scarring causes inversion of the lids (entropion) so that the lashes rub against the cornea (trichiasis). The cornea becomes vascularised and opaque. The problem may not be detected until vision begins to fail.

Investigations and management

Intracellular inclusions may be demonstrated in conjunctival scrapings by staining with iodine or immunofluorescence. Although chlamydiae may, in theory, be isolated in chick embryo or cell culture or detected by nucleic acid amplification tests, these methods are rarely available in the areas where trachoma is encountered, and in any case their sensitivity and specificity are poorly established. Diagnosis of trachoma is therefore based on clinical and epidemiological features.

A single dose of azithromycin (20 mg/kg) has been shown to be superior to 6 weeks of tetracycline eye ointment twice daily for individuals in mass treatment programmes. Deformity and scarring of the lids, and corneal opacities, ulceration and scarring require surgical treatment after control of local infection.

Prevention

Personal and family hygiene should be improved. Proper care of the eyes of newborn and young children is essential. Family contacts should be examined. The WHO is promoting the SAFE strategy for trachoma control (surgery, antibiotics, facial cleanliness and environmental improvement).
Rupture of the schizont releases more merozoites into the blood and causes fever, the periodicity of which depends on the species of parasite.

*P. vivax* and *P. ovale* may persist in liver cells as dormant forms, hypnozoites, capable of developing into merozoites months or years later. Thus the first attack of clinical malaria may occur long after the patient has left the endemic area, and the disease may relapse after treatment with drugs that only kill the erythrocytic stage of the parasite.

*P. falciparum, P. knowlesi* and *P. malariae* have no persistent exo-erythrocytic phase but recrudescence of fever may result from multiplication of parasites in red cells that have not been eliminated by treatment and immune processes (Box 11.53).

**Pathology**

Red cells infected with malaria are prone to haemolysis. This is most severe with *P. falciparum*, which invades red cells of all ages but especially young cells; *P. vivax* and *P. ovale* invade reticulocytes, and *P. malariae* normoblasts, so that infections

remain lighter. Anaemia may be profound and is worsened by dyserythropoiesis, splenomegaly and depletion of folate stores.

In *P. falciparum* malaria, red cells containing trophozoites adhere to vascular endothelium in post-capillary venules in brain, kidney, liver, lungs and gut by the formation of ‘knob’ proteins. They also form ‘rosettes’ and rouleaux with uninfected red cells. Vessel congestion results in organ damage, which is exacerbated by rupture of schizonts, liberating toxic and antigenic substances (Fig. 11.33).

*P. falciparum* has influenced human evolution, with the appearance of protective mutations such as sickle-cell (HbS; p. 951), thalassaemia (p. 953), glucose-6-phosphate dehydrogenase (G6PD) deficiency (p. 948) and HLA-B53. *P. falciparum* does not grow well in red cells that contain haemoglobin F, C or especially S. Haemoglobin S heterozygotes (AS) are protected against the lethal complications of malaria. *P. vivax* cannot enter red cells that lack the Duffy blood group; therefore many West Africans and African Americans are protected.

**Clinical features**

The clinical features of malaria are non-specific and the diagnosis must be suspected in anyone returning from an endemic area who has features of infection.

---

**P. falciparum infection**

This is the most dangerous of the malarials. The onset is often insidious, with malaise, headache and vomiting. Cough and mild diarrhoea are also common. The fever has no particular pattern. Jaundice is common due to haemolysis and hepatic dysfunction. The liver and spleen enlarge and may become tender. Anaemia develops rapidly, as does thrombocytopenia.

A patient with *falciparum* malaria, apparently not seriously ill, may rapidly develop dangerous complications (Fig. 11.34 and Box 11.54). Cerebral malaria is manifested by delirium, seizures or coma, usually without localising signs. Children die rapidly without any specific symptoms other than fever. Immunity is impaired in pregnancy and the parasite can preferentially bind to the placental protein chondroitin sulphate A. Abortion and intrauterine growth retardation from parasitisation of the maternal side of the placenta are frequent. Previous splenectomy increases the risk of severe malaria.

**P. vivax and *P. ovale* infection**

In many cases, the illness starts with several days of continued fever before the development of classical bouts of fever on alternate days. Fever starts with a rigor. The patient feels cold and the temperature rises to about 40°C. After half an hour to

(CPAP = continuous positive airway pressure; PEEP = positive end-expiratory pressure)

---

an hour, the hot or flush phase begins. It lasts several hours and gives way to profuse perspiration and a gradual fall in temperature. The cycle is repeated 48 hours later. Gradually, the spleen and liver enlarge and may become tender. Anaemia develops slowly. Relapses are frequent in the first 2 years after leaving the malarious area and infection may be acquired from blood transfusion.

**P. malariae** and **P. knowlesi** infection

This is usually associated with mild symptoms and bouts of fever every third day. Parasitaemia may persist for many years, with the occasional recrudescence of fever or without producing any symptoms. Chronic *P. malariae* infection causes glomerulonephritis and long-term nephrotic syndrome in children. *P. knowlesi* is usually mild but can deteriorate rapidly.

**Investigations**

Giemsa-stained thick and thin blood films should be examined whenever malaria is suspected. In the thick film, erythrocytes are lysed, releasing all blood stages of the parasite. This, as well as the fact that more blood is used in thick films, facilitates the diagnosis of low-level parasitaemia. A thin film is essential to confirm the diagnosis, species and, in *P. falciparum* infections, to quantify the parasite load (by counting the percentage of infected erythrocytes). *P. falciparum* parasites may be very scanty, especially in patients who have been partially treated. With *P. falciparum*, only ring forms are normally seen in the early stages (Fig. 11.34); with the other species, all stages of the erythrocytic cycle may be found. Gametocytes appear after about 2 weeks, persist after treatment and are harmless, except that they are the source by which more mosquitoes become infected.

Immunochromatographic rapid diagnostic tests (RDTs) for malaria antigens, such as OptiMAL (which detects the *Plasmodium* LDH of *P. falciparum* and *vivax*) and Parasight-F (which detects the *P. falciparum* histidine-rich protein 2), are extremely sensitive and specific for *falciparum* malaria but less so for other species. They should be used in parallel with blood film examination but are especially useful where the microscopist is less experienced in examining blood films (e.g. in the UK). They are less sensitive for low-level parasitaemia and positivity may persist for a month or more in some individuals. The QBC Malaria Test is a fluorescence microscopy-based malaria diagnostic test that is also widely used.

DNA detection (PCR) is used mainly in research and is useful for determining whether a patient has a recrudescence of the same malaria parasite or a reinfection with a new parasite.
Management

Mild *P. falciparum* malaria

Since *P. falciparum* is now resistant to chloroquine and sulfadoxine-pyrimethamine (Fansidar) almost worldwide, an artemisinin-based treatment is recommended (Box 11.55) and WHO policy in Africa recommends always using ACT, e.g. co-artemether or artesunate–amodiaquine. Unfortunately, artemisinin resistance has now been reported in South-east Asia.

Severe malaria

| Preferred therapy |
| Artesunate 2.4 mg/kg IV at 0, 12 and 24 hrs and then once daily for 7 days. Once the patient is able to recommence oral intake, switch to 2 mg/kg orally once daily, to complete a total cumulative dose of 17–18 mg/kg |
| Alternative therapy |
| • Quinine, loading dose 20 mg/kg IV over 4 hrs, up to a maximum of 1.4 g, then maintenance doses of 10 mg/kg quinine salt given as 4-hr infusions 3 times daily for the first 48 hrs then twice a day, up to a maximum of 700 mg per dose or until the patient can take drugs orally. Combine with doxycycline (or clindamycin if there are contraindications to doxycycline) |
| • Note the loading dose should not be given if quinine, quinidine or mefloquine has been administered in the previous 24 hrs |
| • Patients should be monitored by ECG while receiving quinine, with special attention to QRS duration and QT interval |

Non- *falciparum* malaria

| Preferred therapy |
| • Chloroquine: 600 mg chloroquine base orally, followed by 300 mg base in 6 hrs, then 150 mg base twice daily for 2 more days plus primaquine (30 mg orally daily for *P. vivax* or 15 mg orally daily for *P. ovale*) for 14 days after confirming GGPD-negative |
| Patients with mild to moderate GGPD deficiency and *P. vivax* or *P. ovale* |
| • Chloroquine plus primaquine 0.75 mg/kg weekly orally for 8 weeks |
| Chloroquine-resistant *P. vivax* |
| • Co-artemether as for *P. falciparum* |

(GGPD = glucose-6-phosphate dehydrogenase)

Complicated *P. falciparum* malaria

Severe malaria should be considered in any non-immune patient with a parasite count greater than 2% or with complications, and is a medical emergency (see Box 11.54). Management includes early and appropriate antimalarial chemotherapy, active treatment of complications, correction of fluid, electrolyte and acid–base balance, and avoidance of harmful ancillary treatments.

The treatment of choice is intravenous artesunate. Late haemolysis is a treatment side-effect in some patients. Rectal administration of artesunate is also being developed to allow administration in remote rural areas. Quinine salt is the alternative. Exchange transfusion has not been tested in randomised controlled trials but may be beneficial for non-immune patients with persisting high parasitaemias (>10% circulating erythrocytes).

Non- *falciparum* malaria

*P. vivax*, *P. ovale*, *P. knowlesi* and *P. malariae* infections should be treated with oral chloroquine but some chloroquine resistance has been reported from Indonesia. ‘Radical cure’ is achieved in patients with *P. vivax* or *P. ovale* malaria using a course of primaquine, which destroys the hypnozoite phase in the liver. Haemolysis may develop in those who are GGPD-deficient. Cyanosis due to the formation of methaemoglobin in the red cells is more common but not dangerous (see Fig. 7.1, p. 135). All are sensitive to ACTs.

Prevention

Clinical attacks of malaria may be preventable with chemoprophylaxis using chloroquine, atovaquone plus proguanil (Malarone), doxycycline or mefloquine. Box 11.56 gives the recommended doses for protection of the non-immune. The risk of malaria in the area to be visited and the degree of chloroquine resistance guide the recommendations for prophylaxis. Updated recommendations are summarised at fitfortravel.nhs.uk. Fansidar should not be used for chemoprophylaxis, as deaths have occurred from agranulocytosis or Stevens–Johnson syndrome (pp. 1224 and 1254). Mefloquine is useful in areas of multiple drug resistance, such as East and Central Africa and Papua New Guinea. Experience shows it to be safe for at least 2 years but there are several contraindications to its use (Box 11.56).

Expert advice is required for individuals unable to tolerate the first-line agents listed or in whom they are contraindicated. Mefloquine should be started 2–3 weeks before travel to give time for assessment of side-effects. Chloroquine should not be taken continuously as a prophylactic for more than 5 years without regular ophthalmic examination, as it may cause irreversible retinopathy. Pregnant and lactating women may take proguanil or chloroquine safely.

Prevention also involves advice about the use of high-concentration diethyltoluamide (DEET), covering up extremities when out after dark, and sleeping under permethrin-impregnated mosquito nets.

Malaria control in endemic areas

There are major initiatives to reduce and eliminate malaria in endemic areas. Successful programmes combine vector control, including indoor residual spraying, use of long-lasting insecticide-treated bed nets (ITNs) and intermittent preventative therapy (IPT; repeated dose of prophylactic drugs in high-risk groups, such as children and pregnant women, which reduces malaria and anaemia).

Research to produce a fully protective malaria vaccine is ongoing.
the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

**Babesiosis**

Babesiosis is a tick-borne intra-erythrocytic protozoon parasite. There are more than 100 species of *Babesia*, all of which have an animal reservoir, typically either rodents or cattle, and are transmitted to humans via the tick vector *Ixodes scapularis*. Most American cases of babesiosis are due to *B. microti* and most European cases to *B. divergens*. Patients present with fever and malaise 1–4 weeks after a tick bite. Illness may be complicated by haemolytic anaemia. Severe illness is seen in splenectomised patients. The diagnosis is made by blood-film examination. Treatment is with quinine and clindamycin.

**African trypanosomiasis (sleeping sickness)**

African sleeping sickness is caused by trypanosomes (Fig. 11.35) conveyed to humans by the bites of infected tsetse flies, and is unique to sub-Saharan Africa (Fig. 11.36). The incidence of sleeping sickness across Africa has declined by over 60% since 1990 due to better control measures. *Trypanosoma brucei gambiense* trypanosomiasis has a wide distribution in West and Central Africa and accounts for 90% of human African trypanosomiasis (HAT). *T. brucei rhodesiense* trypanosomiasis is found in parts of East and Central Africa. In West Africa, transmission is mainly at the riverside, where the fly rests in the shade of trees; no animal reservoir has been identified for *T. gambiense*. *T. rhodesiense* has a large reservoir in numerous wild animals and transmission takes place in the shade of woods bordering grasslands. Rural populations employed in agriculture, fishing and animal husbandry are susceptible. Local people and tourists visiting forests infested with tsetse flies and animal reservoirs may become infected.

**Clinical features**

A bite by a tsetse fly is painful and commonly becomes inflamed; if trypanosomes are introduced, the site may again become painful and swollen about 10 days later ("trypanosomal chancre"), associated with regional lymphadenopathy. Within 2–3 weeks of infection, the trypanosomes invade the blood stream. The disease is characterised by an early haematolymphatic (stage 1) and a late encephalitic phase (stage 2), in which the parasite crosses the blood–brain barrier and chronic encephalopathy develops.

**Rhodesiense infections**

In these infections, the disease is more acute and severe than in *gambiense* infections, so that, within days or a few weeks, the patient is usually severely ill and may have developed pleural effusions and signs of myocarditis or hepatitis. There may be a petechial rash. The patient may die before there are signs of involvement of the CNS. If the illness is less acute, drowsiness, tremors and coma develop.

¹Choice of regimen is determined by area to be visited, length of stay, level of malaria transmission, level of drug resistance, presence of underlying disease in the traveller and concomitant medication taken. ²Contraindicated in the first trimester of pregnancy, lactation, cardiac conduction disorders, epilepsy, psychiatric disorders; may cause neuropsychiatric disorders. ³Causes photosensitisation and sunburn if high-protection sunblock is not used. ⁴Avoid in pregnancy. ⁵British preparations of chloroquine usually contain 150 mg base, French preparations 100 mg base and American preparations 300 mg base.
Gambiense infections

The distinction between early and late stages may not be apparent in gambiense infections. The disease usually runs a slow course over months or years, with irregular bouts of fever and enlargement of lymph nodes. These are characteristically firm, discrete, rubbery and painless, and are particularly prominent in the posterior triangle of the neck (‘Winterbottom’s sign’). The spleen and liver may become palpable. After some months without treatment, the CNS is invaded. Patients develop headache, altered behaviour, blunting of higher mental functions, insomnia by night and sleepiness by day, delirium and eventually tremors, pareses, wasting, coma and death.

Investigations

Trypanosomiasis should be considered in any febrile patient from an endemic area. In rhodesiense infections, thick and thin malaria blood films will reveal trypanosomes. The trypanosomes may be seen in the blood or from puncture of the primary lesion in the earliest stages of gambiense infections, but it is usually easier to demonstrate them by aspiration of a lymph node. Concentration methods include buffy coat microscopy and miniature anion exchange chromatography.

Due to the cyclical nature of parasitaemia, the diagnosis is often made by demonstration of antibodies using a simple, rapid screening card agglutination trypanosomiasis test (CATT) for gambiense HAT, followed by parasitological confirmation. No reliable serological test is available for rhodesiense HAT. PCR diagnosis is available, although technical requirements limit its availability in endemic regions. If the CNS is affected, the cell count (>20 \times 10^9\text{ leucocytes/L}) and protein content of the CSF are increased and the glucose is diminished. A very high level of serum IgM or the presence of IgM in the CSF is suggestive of trypanosomiasis. Recognition of CNS involvement is critical, as failure to treat it might be fatal.

Management

Therapeutic options for African trypanosomiasis are limited and most antitypansomodal drugs are toxic and expensive. The prognosis is good if treatment is begun early, before the brain has been invaded. At this stage, intravenous suramin, after a test dose of 100–200 mg, should be given for rhodesiense infections, followed by five injections of 20 mg/kg every 7 days. For gambiense infections, deep intramuscular or intravenous pentamidine 4 mg/kg for 7 days is given.

For the treatment of stage 2 (nervous system) infection caused by gambiense HAT, patients were previously treated with melarsoprol (an arsenical). Treatment-related mortality with melarsoprol is 4–12% due to reactive encephalopathy. Now eflornithine (DFMO), an irreversible inhibitor of ornithine decarboxylase (100 and 150 mg/kg IV 4 times daily for 14 days for adults and children, respectively), is a safer and cost-effective option. Combinations of eflornithine (400 mg daily for 7 days) with oral nitritomix (15 mg/kg daily for 15 days) have been shown to decrease relapses, deaths and drug toxicity. Stage 2 rhodesiense infection is treated with melarsoprol 2.2 mg/kg IV for 10 days.

Prevention

In endemic gambiense areas, various measures are taken against tsetse flies, and field teams help detect and treat early HAT. In rhodesiense endemic areas, control is difficult.

American trypanosomiasis (Chagas’ disease)

Chagas’ disease occurs widely in South and Central America. The cause is Trypanosoma cruzi, transmitted to humans from the faeces of a reduvid (triatomite) bug, in which the trypanosomes develop before infecting humans. These bugs live in wild forests in crevices, burrows and palm trees. The Triatoma infestans bug has become domesticated in the Southern Cone countries (Argentina, Brazil, Chile, Paraguay and Uruguay). It lives in the mud and wattle walls and thatched roofs of simple rural houses and emerges at night to feed and defaecate on the sleeping occupants. Infected faeces are rubbed in through the conjunctiva, mucosa of mouth or nose, or abrasions of the skin. Over 100 species of mammal – domestic, peridomestic and wild – may serve as reservoirs of infection. In some areas, blood transfusion accounts for about 5% of cases. Congenital transmission occasionally occurs.

Pathology

The trypanosomes migrate via the blood stream, develop into amastigote forms in the tissues and multiply intracellularly by binary fission. In the acute phase (primarily cell-mediated), inflammation of parasitised, as well as non-parasitised, cardiac muscles and capillaries occurs, resulting in acute myocarditis. In the chronic phase, focal myocardial atrophy, signs of chronic passive congestion and thromboembolic phenomena, cardiomegaly and apical cardiac aneurysm are salient findings. In the digestive form of disease, focal myositis and discontinuous lesions of the intramural myenteric plexus are seen, predominantly in the oesophagus and colon.

Clinical features

Acute phase

Clinical manifestations of the acute phase are seen in only 1–2% of individuals infected before the age of 15 years. Young children (1–5 years) are most commonly affected. The entrance of T. cruzi through an abrasion produces a dusky-red, firm swelling and enlargement of regional lymph nodes. A conjunctival lesion, although less common, is characteristic; the unilateral firm, reddish swelling of the lids may close the eye and constitutes ‘Romanya’s sign’. In a few patients, an acute generalised infection soon appears, with a transient morbilliform or urticarial rash, fever, lymphadenopathy and enlargement of the spleen and liver. In a small minority of patients, acute myocarditis and heart failure or neurological features, including personality changes and signs of meningoencephalitis, may be seen. The acute infection may be fatal to infants.

Chronic phase

About 50–70% of infected patients become seropositive and develop an indeterminate form when no parasitaemia is detectable. They have a normal lifespan with no symptoms but are a natural reservoir for the disease and maintain the life cycle of parasites. After a latent period of several years, 10–30% of chronic cases develop low-grade myocarditis and damage to conducting fibres, which causes cardiomyopathy characterised by cardiac dilatation, arrhythmias, partial or complete heart block and sudden death.

In nearly 10% of patients, damage to Auerbach’s plexus results in dilatation of various parts of the alimentary canal, especially the colon and oesophagus, so-called ‘mega’ disease. Dilatation of the bile ducts and bronchi are also recognised sequelae. Autoimmune processes may be responsible for much of the damage. There are geographical variations of the basic pattern...
Toxoplasma gondii can cause space-occupying lesions with a presentation similar to myocarditis. Investigations

*T. cruzi* is easily detectable in a blood film in the acute illness. In chronic disease, it may be recovered in up to 50% of cases by xenodiagnosis, in which infection-free, laboratory-bred reduviid bugs feed on the patient; subsequently, the hindgut or faeces of the bug are examined for parasites. Parasite DNA detection by PCR in the patient’s blood is a highly sensitive method for documentation of infection and, in addition, can be employed in faeces of bugs used in xenodiagnosis tests to improve sensitivity. Antibody detection is also highly sensitive.

Management and prevention

Parasiticidal agents are used to treat the acute phase, congenital disease and early chronic phase (within 10 years of infection). Nifurtimox is given orally. The dose, which has to be carefully supervised to minimise toxicity while preserving parasiticidal activity, is 10 mg/kg daily orally, divided into three equal doses for 90 days. The paediatric dose is 15 mg/kg daily. Cure rates of 80% in acute disease are obtained. Benznidazole is an alternative, given at a dose of 5 mg/kg daily orally, in two divided doses for 60 days; children receive 10 mg/kg daily. Both nifurtimox and benznidazole are toxic, with adverse reaction rates of 30–55%. Parasiticidal treatment of the chronic phase is usually performed but, in the cardiac or digestive ‘mega’ diseases, does not reverse tissue damage. Surgery may be needed.

Preventative measures include improvement of housing and destruction of reduviid bugs by spraying of houses with insecticides. Blood and organ donors should be screened.

Toxoplasmosis

*Toxoplasma gondii* is an intracellular parasite. The sexual phase of the parasite’s life cycle (Fig. 11.37) occurs in the small intestinal epithelium of the domestic cat. Oöcysts are shed in cat faeces and are spread to intermediate hosts (pigs, sheep and also humans) through widespread contamination of soil. Oöcysts may survive in moist conditions for weeks or months. Once they are ingested, the parasite transforms into rapidly dividing tachyzoites through cycles of asexual multiplication. Microscopic tissue cysts develop containing bradyzoites, which persist for the lifetime of the host. Cats become infected or reinfected by ingesting tissue cysts in prey such as rodents and birds.

Human infection occurs via oöcyst-contaminated soil, salads and vegetables, or by ingestion of raw or under-cooked meats containing tissue cysts. Sheep, pigs and rabbits are the most common meat sources. Outbreaks of toxoplasmosis have been linked to the consumption of unfiltered water. In developed countries, toxoplasmosis is the most common protozoal infection; around 22% of adults in the UK are seropositive. Most primary infections are subclinical; however, toxoplasmosis is thought to account for about 15% of heterophile antibody-negative infectious mononucleosis (p. 241). In India or Brazil, approximately 40–60% of pregnant females are seropositive for *T. gondii*. In HIV-1 infection (p. 320), toxoplasmosis is an important opportunistic infection with considerable morbidity and mortality. Generalised toxoplasmosis has been described after accidental laboratory infection with highly virulent strains.

Clinical features

In most immunocompetent individuals, including children and pregnant women, the infection goes unnoticed. In approximately 10% of patients, it causes a self-limiting illness, most common in adults aged 25–35 years. The presenting feature is usually localised or generalised painless lymphadenopathy. The cervical nodes are primarily involved but mediastinal, mesenteric or retroperitoneal groups may be affected. The spleen is seldom palpable. Most patients have no systemic symptoms but some complain of malaise, fever, fatigue, muscle pain, sore throat and headache. Complete resolution usually occurs within a few months, although symptoms and lymphadenopathy tend to fluctuate unpredictably and some patients do not recover completely for a year or more. Encephalitis, myocarditis, polymyositis, pneumonitis or hepatitis occasionally occur in immunocompetent patients but are more frequent in immunocompromised hosts. Retinochoroiditis (Fig. 11.38) is usually the result of congenital infection but has also been reported in acquired disease.

Congenital toxoplasmosis

Acute toxoplasmosis, mostly subclinical, affects 0.3–1% of pregnant women, with an approximately 60% transmission rate to the fetus, which rises with increasing gestation. Seropositive females infected 6 months before conception have no risk of fetal transmission. Congenital disease affects approximately 40% of infected fetuses, and is more likely and more severe with infection early in gestation (see Box 11.26, p. 235). Many fetal infections are subclinical at birth but long-term sequelae include retinochoroiditis, microcephaly and hydrocephalus.
Protozoal infections

281

There are 21 leishmanial species that cause diverse clinical syndromes, which can be placed into three broad groups:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

Epidemiology and transmission

Although most clinical syndromes are caused by zoonotic transmission of parasites from animals (chiefly canine and rodent reservoirs) to humans through phlebotomine sandfly vectors (Fig. 11.39A), humans are the only known reservoir (anthroponotic person-to-person transmission) in major VL foci in the Indian subcontinent and in injection drug-users (Fig. 11.39B and C).

Leishmaniasis

Leishmaniasis is caused by unicellular, flagellate, intracellular protozoa belonging to the genus *Leishmania* (order Kinetoplastidae). There are 21 leishmanial species that cause diverse clinical syndromes, which can be placed into three broad groups:

- visceral leishmaniasis (VL, kala-azar)
- cutaneous leishmaniasis (CL)
- mucosal leishmaniasis (ML).

Investigations

In contrast to immunocompromised patients, in whom the diagnosis often requires direct detection of parasites, serology is often used in immunocompetent individuals. The Sabin–Feldman dye test (indirect fluorescent antibody test), which detects IgG antibody, is most commonly used. Recent infection induces a fourfold or greater increase in titre when paired sera are tested in parallel. Peak titres of 1/1000 or more are reached within 1–2 months of the onset of infection, and serology then becomes an unreliable indicator of recent infection. The detection of significant levels of *Toxoplasma*-specific IgM antibody may be useful in confirming acute infection. A false-positive result or persistence of IgM antibodies for years after infection makes interpretation difficult; however, negative IgM antibodies virtually rule out acute infection.

During pregnancy, it is critical to differentiate recent from past infection; the presence of high-avidity IgG antibodies excludes infection acquired in the preceding 3–4 months.

If necessary, the presence of *Toxoplasma* organisms in a lymph node biopsy or other tissue can be detected histochemically with *T. gondii* antiserum, or by the use of PCR to detect *Toxoplasma*-specific DNA.

Management

In immunocompetent subjects, uncomplicated toxoplasmosis is self-limiting and responds poorly to antimicrobial therapy. Treatment with sulfadiazine, pyrimethamine and folic acid is usually reserved for severe or progressive disease, and for infection in immunocompromised patients.

In pregnant women with established recent infection, spiramycin (3 g daily in divided doses) is given until term. Once fetal infection is established, treatment with sulfadiazine and pyrimethamine plus calcium folinate is recommended (spiramycin does not cross the placental barrier). The cost/benefit of routine *Toxoplasma* screening and treatment in pregnancy is being debated in many countries. There is insufficient evidence to determine the effects on mother or baby of current antiparasitic treatment for women who seroconvert in pregnancy.
may become afebrile for intervening periods ranging from weeks to months. This is followed by a relapse of fever, often of lesser intensity. Splenomegaly develops quickly in the first few weeks and becomes massive as the disease progresses. Moderate hepatomegaly occurs later. Lymphadenopathy is common in Africa, the Mediterranean and South America but is rare in the Indian subcontinent. Blackish discoloration of the skin, from which the disease derived its name, kala-azar (the Hindi word for ‘black fever’), is a feature of advanced illness but is now rarely seen. Pancytopenia is common. Moderate to severe anaemia develops rapidly and can cause cardiac failure. Thrombocytopenia, often compounded by hepatic dysfunction, may result in bleeding from the retina, gastrointestinal tract and nose. In advanced illness, hypoalbuminaemia may manifest as pedal oedema, ascites and anasarca (gross generalised oedema and swelling).

As disease progresses, there is profound immunosuppression and secondary infections are very common. These include tuberculosis, pneumonia, gastroenteritis, severe amoebic or bacillary dysentery, boils, cellulitis, chickenpox, shingles and scabies. Without adequate treatment, most patients with clinical VL die.

Investigations

Pancytopenia is the dominant feature, with granulocytopenia and monocytosis. Polyclonal hypergammaglobulinaemia, chiefly IgG followed by IgM, and hypoalbuminaemia are seen later.

Demonstration of amastigotes (Leishman–Donovan bodies) in splenic smears is the most efficient means of diagnosis, with 98% sensitivity (Fig. 11.42); however, it carries a risk of serious haemorrhage in inexperienced hands. Safer methods, such as bone marrow or lymph node smears, are not as sensitive but
are frequently employed. Parasites may be demonstrated in buffy coat smears, especially in immunosuppressed patients. Sensitivity is improved by culturing the aspirate material or by using PCR for DNA detection and species identification, but these tests can only be performed in specialised laboratories. Serodiagnosis, by ELISA or immunofluorescence antibody test, is employed in developed countries. In endemic regions, a highly sensitive direct agglutination test using stained promastigotes and an equally efficient rapid immunochromatographic k39 strip test have become popular. These tests remain positive for several months after cure has been achieved, so do not predict response to treatment or relapse. The vast majority of people exposed to the parasite do not develop clinical illness but may have positive serological tests thereafter. Formal gel (aldehyde) or other similar tests based on the detection of raised globulin have limited value and should not be employed for the diagnosis of VL.

Differential diagnosis
This includes malaria, typhoid, tuberculosis, schistosomiasis and many other infectious and neoplastic conditions, some of which may coexist with VL. Fever, splenomegaly, pancytopenia and non-response to antimalarial therapy may provide clues before specific laboratory diagnosis is made.

Management
Pentavalent antimonials
Antimony (Sb) compounds were the first drugs to be used for the treatment of leishmaniasis and remain the mainstay of treatment in most parts of the world. The exception is the Indian subcontinent, especially Bihar state, where almost two-thirds of cases are refractory to Sb treatment. Traditionally, pentavalent antimony is available as sodium stibogluconate (100 mg/mL) in English-speaking countries and meglumine antimonite (85 mg/mL) in French-speaking ones. The daily dose is 20 mg/kg body weight, intravenously or intramuscularly, for 28–30 days. Side-effects are common and include arthralgia, myalgia, raised hepatic transaminases, pancreatitis (especially in patients co-infected with HIV) and ECG changes (T-wave inversion and reduced amplitude). Severe cardiotoxicity, manifest by concave ST segment elevation, prolongation of QTc greater than 0.5 msec and ventricular dysrhythmias, is not uncommon. The incidence of cardiotoxicity and death is particularly high with improperly manufactured Sb.

Amphotericin B
Amphotericin B deoxycholate, given once daily or on alternate days at a dose of 0.75–1.00 mg/kg for 15–20 doses, is used as the first-line drug in many regions where there is a significant level of Sb unresponsiveness. It has a cure rate of nearly 100%. Infusion-related side-effects, such as high fever with rigor, thrombophlebitis, diarrhea and vomiting, are extremely common. Serious side-effects, including renal or hepatic toxicity, hypokalaemia and thrombocytopenia, are observed frequently.

Lipid formulations of amphotericin B (p. 126) are less toxic. AmBisome is first-line therapy in Europe for VL. Dosing recommendations vary according to geographical region. In the Indian subcontinent, a total dose of 10 or 15 mg/kg, administered in a single dose or as multiple doses over several days, respectively, is considered adequate, whereas in Africa 14–18 mg/kg, and in South America and Europe 21–24 mg/kg, in divided doses, typically spread over 10 days, is recommended for immunocompetent patients. High daily doses of the lipid formulations are well tolerated, and in one study a single dose of 10 mg/kg of AmBisome cured 96% of Indian patients. The manufacturer of AmBisome has donated a large quantity of the drug for use in the Kala-azar Elimination Programme in India, Nepal and Bangladesh, leading to its adoption as the first-line drug in treatment.

Other drugs
The oral drug miltefosine, an alkyl phospholipid, has been approved in several countries for the treatment of VL. A daily dose of 50 mg (patient’s body weight <25 kg) to 100 mg (≥25 kg), or 2.5 mg/kg for children, for 28 days cures over 90% of patients. Side-effects include mild to moderate vomiting and diarrhoea, and rarely skin allergy or renal or liver toxicity. Since it is a teratogenic drug, it cannot be used in pregnancy; female patients are advised not to become pregnant for the duration of treatment and 3 months thereafter because of its half-life of nearly 1 week. Paromomycin is an aminoglycoside that has undergone trials in India and Africa, and is highly effective if given intramuscularly at 11 mg/kg of paromomycin base, daily for 3 weeks. No significant auditory or renal toxicity is seen. The drug is approved in India for VL treatment.

Pentamidine isethionate was used to treat Sb-refractory patients with VL. However, declining efficacy and serious side-effects, such as type 1 diabetes mellitus, hypoglycaemia and hypotension, have led to it being abandoned.

Multidrug therapy of VL is likely to be used increasingly to prevent emergence of drug resistance, and in India short-course combinations (a single dose of AmBisome 5 mg/kg with either 7 days of miltefosine or 10 days of paromomycin, or 10 days each of miltefosine and paromomycin) were as effective as standard therapy. In India, in treatment centres where the cold chain (a temperature-controlled supply chain) is not maintained, 10 days of paromomycin combined with miltefosine is an alternative treatment regimen.

Response to treatment
A good response results in fever resolution, improved well-being, reduction in splenomegaly, weight gain and recovery of blood counts. Patients should be followed regularly for 6–12 months, as some may experience relapse irrespective of the treatment regimen.

HIV–visceral leishmaniasis co-infection
HIV-induced immunosuppression (Ch. 12) increases the risk of contracting VL 100–1000 times. Most cases of HIV–VL co-infection have been reported from Spain, France, Italy and Portugal. Antiretroviral therapy (ART) has led to a remarkable decline in the incidence of VL co-infection in Europe. However, numbers are increasing in Africa (mainly Ethiopia), Brazil and the Indian subcontinent.

Although the clinical triad of fever, splenomegaly and hepatomegaly is found in the majority of co-infected patients, those with low CD4 count may have atypical clinical presentations. VL may present with gastrointestinal involvement (stomach, duodenum or colon), ascites, pleural or pericardial effusion, or involvement of lungs, tonsil, oral mucosa or skin. Diagnostic principles remain the same as those in non-HIV patients. Parasites are numerous and easily demonstrable, even in buffy coat preparations. Sometimes amastigotes are found in unusual sites, such as bronchoalveolar lavage fluid, pleural fluid or biopsies of the gastrointestinal tract. Serological tests have low sensitivity. DNA detection by PCR of the blood or its buffy coat is at least 95% sensitive and accurately tracks recovery and relapse.
Treatment of VL with HIV co-infection is essentially the same as in immunocompetent patients but there are some differences in outcome. Conventional amphotericin B (0.7 mg/kg/day for 28 days) may be more effective in achieving initial cure than Sb (20 mg/kg/day for 28 days). Using high-dose liposomal amphotericin B (4 mg/kg on days 1–5, 10, 17, 24, 31 and 38), a high cure rate is possible. However, co-infected patients have a tendency to relapse within 1 year and maintenance chemotherapy with monthly liposomal amphotericin B is useful.

**Post-kala-azar dermal leishmaniasis**

After treatment and apparent recovery from VL in India and Sudan, some patients develop dermatological manifestations due to local parasitic infection.

**Clinical features**

In India, dermatological changes occur in a small minority of patients 6 months to at least 3 years after the initial infection. They are seen as macules, papules, nodules (most frequently) and plaques, which have a predilection for the face, especially the area around the chin. The face often appears erythematous (Fig. 11.43A). Hypopigmented macules can occur over all parts of the body and are highly variable in extent. There are no systemic symptoms and little spontaneous healing occurs.

In Sudan, approximately 50% of patients with VL develop post-kala-azar dermal leishmaniasis (PKDL), experiencing skin manifestations concurrently with VL or within the following 6 months. In addition to the dermatological features, a measles-like micropapular rash (Fig. 11.43B) may be seen all over the body. In Sudan, children are more frequently affected than in India. Spontaneous healing occurs in about three-quarters of cases within 1 year.

**Investigations and management**

The diagnosis is clinical, supported by demonstration of scanty parasites in lesions by slit-skin smear and culture. Immunofluorescence and immunohistochemistry may demonstrate the parasite in skin tissues. In the majority of patients, serological tests (direct agglutination test or k39 strip tests) are positive.

Treatment of PKDL is difficult. In India, Sb for 120 days, several courses of amphotericin B infusions, or miltefosine for 12 weeks is required. In Sudan, Sb for 2 months is considered adequate. In the absence of a physical handicap, most patients are reluctant to complete the treatment. PKDL patients are a human reservoir, and focal outbreaks have been linked to patients with PKDL in areas previously free of VL.

**Prevention and control**

Sandfly control through insecticide spray is very important. Mosquito nets or curtains treated with insecticides will keep out the tiny sandflies. In endemic areas with zoonotic transmission, infected or stray dogs should be destroyed.

In areas with anthropoponic transmission, early diagnosis and treatment of human infections, to reduce the reservoir and control epidemics of VL, is extremely important. Serology is useful in diagnosis of suspected cases in the field. No vaccine is currently available.

**Cutaneous and mucosal leishmaniasis**

**Cutaneous leishmaniasis**

CL (oriental sore) occurs in both the Old World (Asia, Africa and Europe) and the New World (the Americas). Transmission is described on page 281.

In the Old World, CL is mild. It is found around the Mediterranean basin, throughout the Middle East and Central Asia as far as Pakistan, and in sub-Saharan West Africa and Sudan (Fig. 11.44). The causative organisms for Old World zoonotic CL are *L. major*, *L. tropica* and *L. aethiopica* (Box 11.57). Anthropoponic CL is caused by *L. tropica*, and is confined to urban or suburban areas of the Old World. Afghanistan is currently the biggest focus but infection is endemic in Pakistan, the western deserts of India, Iran, Iraq, Syria and other areas of the Middle East. In recent years, there has been an increase in the incidence of zoonotic CL in both the Old and the New Worlds due to urbanisation and deforestation, which led to peridomestic transmission (in and around human dwellings).
Protozoal infections • 285

New World CL is a more significant disease, which may disfigure the nose, ears and mouth, and is caused by the *L. mexicana* complex (comprising *L. mexicana*, *L. amazonensis* and *L. venezuelensis*) and by the Viannia subgenus *L. (V.) braziliensis* complex (comprising *L. (V.) guyanensis*, *L. (V.) panamensis*, *L. (V.) braziliensis* and *L. (V.) peruviana*).

CL is commonly imported and should be considered in the differential diagnosis of an ulcerating skin lesion, especially in travellers who have visited endemic areas of the Old World or forests in Central and South America.

**Pathogenesis**

Inoculated parasites are taken up by dermal macrophages, in which they multiply and form a focus for lymphocytes, epithelioid cells and plasma cells. Self-healing may occur with necrosis of infected macrophages, or the lesion may become chronic with ulceration of the overlying epidermis, depending on the aetiological pathogen.

**Clinical features**

The incubation period is typically 2–3 months (range 2 weeks to 5 years). In all types of CL a papule develops at the site of the vector bite. The small, red papules may be single or multiple and increase gradually in size, reaching 2–10 cm in diameter. A crust forms, overlying an ulcer with a granular base and with raised borders (Fig. 11.45). These ulcers develop a few weeks or months after the bite. There can be satellite lesions, especially in *L. major* and occasionally in *L. tropica* infections. Regional lymphadenopathy, pain, pruritus and secondary bacterial infections may occur.

Lesions of *L. mexicana* and *L. peruviana* closely resemble those seen in the Old World, but lesions on the pinna of the ear are common and are chronic and destructive. *L. mexicana* is responsible for chichero ulcers, the self-healing sores of Mexico.

If immunity is effective, there is usually spontaneous healing in *L. tropica*, *L. major* and *L. mexicana* lesions. In some patients with anergy to Leishmania, the skin lesions of *L. aethiopica*, *L. mexicana* and *L. amazonensis* infections progress to the development of diffuse CL; this is characterised by spread of the infection from the initial ulcer, usually on the face, to involve the whole body in the form of non-ulcerative nodules. Occasionally, in *L. tropica* infections, sores that have apparently healed relapse persistently (recidivans or lupoid leishmaniasis).

**Mucosal leishmaniasis**

The Viannia subgenus extends widely from the Amazon basin as far as Paraguay and Costa Rica, and is responsible for deep sores and ML. In *L. (V.) braziliensis* complex infections, cutaneous lesions may be followed by mucosal spread of the disease simultaneously or even years later. Young men with chronic lesions are particularly at risk, and 2–40% of infected persons develop ‘espundia’, metastatic lesions in the mucosa of the nose or mouth. This is characterised by thickening and erythema of the nasal mucosa, typically starting at the junction of the nose and upper lip. Later, ulceration develops. The lips, soft palate, fauces and larynx may also be invaded and destroyed, leading to considerable suffering and deformity. There is no spontaneous healing, and death may result from severe respiratory tract infections due to massive destruction of the pharynx.

**Investigations in CL and ML**

CL is often diagnosed on the basis of the lesions’ clinical characteristics. Parasitological confirmation is important, however, because clinical manifestations may be mimicked by other infections. Amastigotes can be demonstrated on a slit-skin smear with Giemsa staining; alternatively, they can be cultured from the sores early during the infection. Parasites seem to be particularly
difficult to isolate from sores caused by \textit{L. brasilensis}, responsible for the vast majority of cases in Brazil. Touch preparations from biopsies and histopathology usually have a low sensitivity. Culture of fine needle aspiration material has been reported to be the most sensitive method.

ML is more difficult to diagnose parasitologically. The leishmanin skin test measures delayed-type hypersensitivity to killed \textit{Leishmania} organisms. A positive test is defined as induration of more than 5 mm, 48 hours after intradermal injection. The test is positive, except in diffuse CL and during active VL. PCR is used increasingly for diagnosis and speciation, which is useful in selecting therapy.

**Management of CL and ML**

Small lesions may self-heal or are treated by freezing with liquid nitrogen or curettage. There is no ideal antimicrobial therapy. Treatment should be individualised on the basis of the causative organism, severity of the lesions, availability of drugs, tolerance of the patient for toxicity, and local resistance patterns.

In CL, topical application of paromomycin 15% plus methylbenzethonium chloride 12% is beneficial. Intraleisonal antimony (Sb 0.2–0.8 mL/lesion) up to 2 g seems to be rapidly effective in suitable cases; it is well tolerated and economic, and is safe in patients with cardiac, liver or renal diseases.

In ML, and in CL when the lesions are multiple or in a disfiguring site, it is better to treat with parenteral Sb in a dose of 20 mg/kg/day (usually given for 20 days for CL and 28 days for ML), or with conventional or liposomal amphotericin B (see treatment of VL above). Sb is also indicated to prevent the development of mucosal disease, if there is any chance that a lesion acquired in South America is due to an \textit{L. brasilensis} strain. Refractory CL or ML should be treated with an amphotericin B preparation. Other regimens may be effective. Two to four doses of pentamidine (2–4 mg/kg), administered on alternate days, are effective in New World CL caused by \textit{L. guyanensis}. In ML, 8 injections of pentamidine (4 mg/kg on alternate days) cure the majority of patients. Ketoconazole (600 mg daily for 4 weeks) has shown some potential against \textit{L. mexicana} infection. In Saudi Arabia, fluconazole (200 mg daily for 6 weeks) reduced healing times and cured 79% of patients with CL caused by \textit{L. major}. In India, itraconazole (200 mg daily for 6 weeks) produced good results in CL.

**Prevention of CL and ML**

Personal protection against sandfly bites is important. No effective vaccine is yet available.

**Gastrointestinal protozoal infections**

**Amoebiasis**

Amoebiasis is caused by \textit{Entamoeba histolytica}, which is spread between humans by its cysts. It is one of the leading parasitic causes of morbidity and mortality in the tropics and is occasionally acquired in non-tropical countries. Two non-pathogenic \textit{Entamoeba} species (\textit{E. dispar} and \textit{E. moshkovskii}) are morphologically identical to \textit{E. histolytica}, and are distinguishable only by molecular techniques, isoenzyme studies or monoclonal antibody typing. However, only \textit{E. histolytica} causes amoebic dysentery or liver abscess. The life cycle of the amoeba is shown in Figure 11.46A.

**Pathology**

Cysts of \textit{E. histolytica} are ingested in water or uncooked foods contaminated by human faeces. Infection may also be acquired through anal/oral sexual practices. In the colon, trophozoite forms emerge from the cysts. The parasite invades the mucous membrane of the large bowel, producing lesions that are maximal

---

**Fig. 11.46 Amoebiasis.** **A** The life cycle of \textit{Entamoeba histolytica}. **B** The chocolate-brown appearance of aspirated material from an amoebic liver abscess. **A** From Knight R. Parasitic disease in man. Churchill Livingstone, Elsevier Ltd, 1982. **B** Courtesy of Dr Ravi Gowda, Royal Hallamshire Hospital, Sheffield.
in the caecum but extend to the anal canal. These are flask-shaped ulcers, varying greatly in size and surrounded by healthy mucosa. A localized granuloma (amoeboma), presenting as a palpable mass in the rectum or a filling defect in the colon on radiography, is a rare complication that should be differentiated from carcinoma. Amoebic ulcers may cause severe haemorrhage but rarely perforate the bowel wall.

Amoebic trophozoites can emerge from the vegetative cyst from the bowel and be carried to the liver in a portal venule. They can multiply rapidly and destroy the liver parenchyma, causing an abscess (see also p. 879). The liquid contents at first have a characteristic pinkish colour, which may later change to chocolate-brown (said to resemble anchovy sauce).

Cutaneous amoebiasis, though rare, causes progressive genital, perianal or peri-abdominal surgical wound ulceration.

**Clinical features**

**Intestinal amoebiasis – amoebic dysentery**

Most amoebic infections are asymptomatic. The incubation period of amoebiasis ranges from 2 weeks to many years, followed by a chronic course with abdominal pains and two or more unformed stools a day. Offensive diarrhoea, alternating with constipation, and blood or mucus in the stool are common. There may be abdominal pain, especially in the right lower quadrant (which may mimic acute appendicitis). A dysenteric presentation with passage of blood, simulating bacillary dysentery or ulcerative colitis, occurs particularly in older people, in the puerperium and with super-added pyogenic infection of the ulcers.

**Amoebic liver abscess**

The abscess is usually found in the right hepatic lobe. There may not be associated diarrhoea. Early symptoms may be only local discomfort and malaise; later, a swinging temperature and sweating may develop, usually without marked systemic symptoms or signs. An enlarged, tender liver, cough and pain in the right shoulder are characteristic but symptoms may remain vague and signs minimal. A large abscess may penetrate the diaphragm, rupturing into the lung, and may be coughed up through a hepatobronchial fistula. Rupture into the pleural or peritoneal cavity, or rupture of a left lobe abscess in the pericardial cavity, is less common but more serious.

**Investigations**

The stool and any exudate should undergo prompt microscopic examination for motile trophozoites containing red blood cells. Movements cease rapidly as the stool preparation cools. Several stools may need to be examined in chronic amoebiasis before cysts are found. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica*. In endemic areas, one-third of the population are symptomless passers of amoebic cysts.

An amoebic abscess of the liver is suspected on clinical grounds; there is often a neutrophil leucocytosis and a raised right hemidiaphragm on chest X-ray. Confirmation is by ultrasonic examination for motile trophozoites containing red blood cells. Sigmoidoscopy may reveal typical flask-shaped ulcers, which should be scraped and examined immediately for *E. histolytica*. In endemic areas, one-third of the population are symptomless passers of amoebic cysts.

**Management**

Intestinal and early hepatic amoebiasis responds quickly to oral metronidazole (800 mg 3 times daily for 5–10 days) or other long-acting nitroimidazoles like tinidazole or ornidazole (both in doses of 2 g daily for 3 days). Nitazoxanide (500 mg twice daily for 3 days) is an alternative drug. Either diloxanide furate or paromomycin, in doses of 500 mg orally 3 times daily for 10 days after treatment, should be given to eliminate luminal cysts.

If a liver abscess is large or threatens to burst, or if the response to chemotherapy is not prompt, aspiration is required and is repeated if necessary. Rupture of an abscess into the pleural cavity, pericardial sac or peritoneal cavity necessitates immediate aspiration or surgical drainage. Small serous effusions resolve without drainage.

**Prevention**

Personal precautions against contracting amoebiasis include not eating fresh, uncooked vegetables or drinking unclean water.

### Giardiasis

Infection with *Giardia lamblia* is found worldwide and is common in the tropics. It particularly affects children, tourists and immunosuppressed individuals, and is the parasite most commonly imported into the UK. In cystic form, it remains viable in water for up to 3 months and infection usually occurs by ingesting contaminated water. Its flagellar trophozoite form attaches to the duodenal and jejunal mucosa, causing inflammation.

**Clinical features and investigations**

After an incubation period of 1–3 weeks, there is diarrhoea, abdominal pain, weakness, anorexia, nausea and vomiting. On examination, there may be abdominal distension and tenderness. Chronic diarrhoea and malabsorption may occur, with bulky stools that float.

Stools obtained at 2–3-day intervals should be examined for cysts. Duodenal or jejunal aspiration by endoscopy gives a higher diagnostic yield. The ‘string test’ may be used, in which one end of a piece of string is passed into the duodenum by swallowing and retrieved after an overnight fast; expressed fluid is then examined for the presence of *G. lamblia* trophozoites. A number of stool antigen detection tests are available. Jejunal biopsy specimens may show *G. lamblia* on the epithelial surface.

**Management**

Treatment is with a single dose of tinidazole 2 g, metronidazole 400 mg 3 times daily for 10 days, or nitazoxanide 500 mg orally twice daily for 3 days.

### Cryptosporidiosis

Cryptosporidium spp. are coccidian protozoal parasites of humans and domestic animals. Infection is acquired by the faecal–oral route through contaminated water supplies. The incubation period is approximately 7–10 days and is followed by watery diarrhoea and abdominal cramps. The illness is usually self-limiting but in immunocompromised patients, especially those with HIV, the illness can be devastating, with persistent severe diarrhoea and substantial weight loss (p. 317).

### Cyclosporiasis

*Cyclospora cayetanensis* is a globally distributed coccidian protozoal parasite of humans. Infection is acquired by ingestion
of contaminated water and recent food-borne outbreaks have been associated with raspberries and coriander (cilantro). The incubation period of approximately 2–11 days is followed by diarrhoea with abdominal cramps, which may remit and relapse. Although usually self-limiting, the illness may last as long as 6 weeks, with significant weight loss and malabsorption, and is more severe in immunocompromised individuals. Diagnosis is by detection of oöcysts on faecal microscopy or PCR of stool. Treatment may be necessary in a few cases, using co-trimoxazole 960 mg twice daily for 7 days.

**Infections caused by helminths**

Helminths (from the Greek *helmins*, meaning worm) include three groups of parasitic worm (Box 11.58), large multicellular organisms with complex tissues and organs.

**Intestinal human nematodes**

Adult nematodes living in the human gut can cause disease. There are two types:

- the hookworms, which have a soil stage in which they develop into larvae that then penetrate the host
- a group of nematodes that survive in the soil merely as eggs, which have to be ingested for their life cycle to continue.

The geographical distribution of hookworms is limited by the larval requirement for warmth and humidity. Soil-transmitted nematode infections can be prevented by avoidance of faecal soil contamination (adequate sewerage disposal) or skin contact (wearing shoes), and by strict personal hygiene.

**Ancylostomiasis (hookworm)**

Ancylostomiasis is caused by *Ancylostoma duodenale* or *Necator americanus*. The complex life cycle is shown in Figure 11.47. The adult hookworm is 1 cm long and lives in the duodenum and upper jejunum. Eggs are passed in the faeces. In warm, moist, shady soil, the larvae develop into rhabditiform and then the infective filariform stages; they then penetrate human skin and are carried to the lungs. After entering the alveoli, they ascend the bronchi, are swallowed and mature in the small intestine, reaching maturity 4–7 weeks after infection. The worms attach to the mucosa of the small intestine by their buccal capsule (Fig. 11.48) and withdraw blood. The mean daily blood loss from one *A. duodenale* is 0.15 mL and that from *N. americanus* 0.03 mL. Hookworm infection is a leading cause of anaemia in the tropics and subtropics.

*A. duodenale* is endemic in the Far East and Mediterranean coastal regions, and is also present in Africa, while *N. americanus* is endemic in West, East and Central Africa, and Central and South America, as well as in the Far East.

---

**Box 11.58 Classes of helminth that parasitise humans**

**Nematodes or roundworms**

- Intestinal human nematodes: *Ancylostoma duodenale*, *Necator americanus*, *Strongyloides stercoralis*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Trichuris trichiura*
- Tissue-dwelling human nematodes: *Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, *Onchocerca volvulus*, *Dracunculus medinensis*, *Mansonella perstans*, *Dirofilaria immitis*
- Zoonotic nematodes: *Trichinella spiralis*

**Trematodes or flukes**

- Blood flukes: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi*, *S. intercalatum*
- Lung flukes: *Paragonimus spp.*
- Hepatobiliary flukes: *Clonorchis sinensis*, *Fasciola hepatica*, *Opisthorchis felineus*
- Intestinal flukes: *Fasciolopsis buski*

**Cestodes or tapeworms**

- Intestinal tapeworms: *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*
- Tissue-dwelling cysts or worms: *Taenia solium*, *Echinococcus granulosus*

Fig. 11.47 Ancylostomiasis. Life cycle of *Ancylostoma*.

Fig. 11.48 *Ancylostoma duodenale*. Electron micrograph showing the ventral teeth. From Gibbons LM. SEM guide to the morphology of nematode parasites of vertebrates. Farnham Royal, Slough: Commonwealth Agricultural Bureau International; 1986.
**Clinical features**

An allergic dermatitis, usually on the feet (ground itch), may be experienced at the time of infection. The passage of the larvae through the lungs in a heavy infection causes a paroxysmal cough with blood-stained sputum, associated with patchy pulmonary consolidation and eosinophilia. When the worms reach the small intestine, vomiting and epigastric pain resembling peptic ulcer disease may occur. Sometimes, frequent loose stools are passed. The degree of iron and protein deficiency depends not only on the worm burden but also on patient nutrition and iron stores. Anaemia with high-output cardiac failure may result. The mental and physical development of children may be delayed in severe infection.

**Investigations**

There is eosinophilia. The characteristic ovum can be recognised in the stool. If hookworms are present in numbers sufficient to cause anaemia, faecal occult blood testing will be positive.

**Management**

A single dose of albendazole (400 mg) is the treatment of choice. Alternatively, mebendazole 100 mg twice daily for 3 days may be used. Anaemia and heart failure associated with hookworm infection respond well to oral iron, even when severe; blood transfusion is rarely required.

**Strongyloidiasis (threadworm)**

*Strongyloides stercoralis* is a small nematode (2 mm \times 0.4 mm) that parasitises the mucosa of the upper part of the small intestine, often in large numbers, causing persistent eosinophilia. The eggs hatch in the bowel but only larvae are passed in the faeces. In moist soil, they moult and become the infective filariform larvae. After penetrating human skin, they undergo a development cycle similar to that of hookworms, except that the female worms burrow into the intestinal mucosa and submucosa. Some larvae in the intestine may develop into filariform larvae, which may then penetrate the mucosa or the perianal skin and lead to autoinfection and persistent infection. Patients with *Strongyloides* infection persisting for more than 35 years have been described. Strongyloidiasis occurs in the tropics and subtropics, and is especially prevalent in the Far East.

**Clinical features**

These are shown in Box 11.59. The classic triad of symptoms consists of abdominal pain, diarrhoea and urticaria. Cutaneous manifestations, either urticaria or larva currens (a highly characteristic pruritic, elevated, erythematous lesion, rapidly advancing along the course of larval migration), are characteristic and occur in 66% of patients.

Systemic strongyloidiasis (the *Strongyloides* hyperinfection syndrome), with dissemination of larvae throughout the body, occurs with immune suppression (HIV or HTLV-1 infection, immunosuppressant treatment). Patients present with severe, generalised abdominal pain, abdominal distension and shock. Massive larval invasion of the lungs causes cough, wheeze and dyspnoea; cerebral involvement has manifestations ranging from subtle neurological signs to coma. Gram-negative sepsis frequently complicates the picture.

**Investigations**

There is eosinophilia. Serology (ELISA) is helpful but definitive diagnosis depends on finding the larvae. The faeces should be examined microscopically for motile larvae; excretion is intermittent and so repeated examinations are necessary. Larvae may be found in jejunal aspirates or detected using the string test (p. 287). Larvae may also be cultured from faeces.

**Management**

A course of two doses of ivermectin (200 μg/kg), administered on successive days, is effective. Alternatively, albendazole is given orally (15 mg/kg twice daily for 3 days). A second course may be required. For the *Strongyloides* hyperinfection syndrome, ivermectin is given at 200 μg/kg for 5–7 days.

**Ascaris lumbricoides (roundworm)**

This pale yellow nematode is 20–35 cm long. Humans are infected by eating food contaminated with mature ova. *Ascaris* larvae hatch in the duodenum, migrate through the lungs, ascend the bronchial tree, are swallowed and mature in the small intestine. This tissue migration can provoke both local and general hypersensitivity reactions, with pneumonitis, eosinophilic granulomas, wheezing and urticaria.

**Clinical features**

Intestinal ascariasis causes symptoms ranging from vague abdominal pain to malnutrition. The large size of the adult worm and its tendency to aggregate and migrate cause obstructive complications. Tropical and subtropical areas are endemic for ascariasis, and here it causes up to 35% of all intestinal obstructions, most commonly in the terminal ileum. Obstruction can be complicated further by intussusception, volvulus, haemorrhagic infarction and perforation. Other complications include blockage of the bile or pancreatic duct and obstruction of the appendix by adult worms. Ascariasis in non-endemic areas has been associated with pig husbandry and may be caused by *Ascaris suum*, which is indistinguishable from (and possibly the same species as) *Ascaris lumbricoides*.

**Investigations**

The diagnosis is made microscopically by finding ova in the faeces. Adult worms are frequently expelled rectally or orally. Occasionally, the worms are demonstrated radiographically by a barium examination. There is eosinophilia.

**Management**

A single dose of albendazole (400 mg), pyrantel pamoate (11 mg/kg; maximum 1 g), or ivermectin (150–200 μg/kg), or alternatively mebendazole (100 mg twice daily for 3 days)
treats intestinal ascariasis. Patients should be warned that they might expel numerous whole, large worms. Obstruction due to ascariasis should be treated with nasogastric suction, piperazine and intravenous fluids. Complete intestinal obstruction and its complications require urgent surgical intervention.

Prevention
Community chemotherapy programmes reduce Ascaris infection. The whole community can be treated every 3 months for several years. Alternatively, schoolchildren are targeted; treating them lowers the prevalence of ascariasis in the community.

Enterobius vermicularis (threadworm)

This helminth is common worldwide and affects mainly children. After the ova are swallowed, development takes place in the small intestine but the adult worms are found chiefly in the colon.

Clinical features
The female lays ova around the anus, causing intense itching, especially at night. The ova are often carried to the mouth on the fingers and so reinfection or human-to-human infection occurs (Fig. 11.49). In females, the genitalia may be involved. The adult worms may be seen moving on the buttocks or in the stool.

Investigations
Ova are detected in stool samples or by applying the adhesive surface of cellophane tape to the perianal skin in the morning. This is then examined on a glass slide under the microscope. A perianal swab, moistened with saline, also allows diagnosis.

Management
A single dose of mebendazole (100 mg), albendazole (400 mg), pyrantel pamoate (11 mg/kg) or piperazine (4 g) treats infection and is repeated after 2 weeks to control auto-reinfection. If infection recurs in a family, each member should be treated. Fingernails must be kept short and hands washed carefully before meals. Subsequent therapy is reserved for family members with recurrent infection.

Trichuris trichiura (whipworm)

Whipworm infections are common worldwide with poor hygiene. Infection follows ingestion of earth or food contaminated with ova, which have become infective after lying for 3 weeks or more in moist soil. The adult worm is 3–5 cm long and has a coiled anterior end resembling a whip. Whipworms inhabit the caecum, ileum, appendix, colon and anal canal. There are usually no symptoms, but intense infections in children may cause persistent diarrhoea or rectal prolapse, and growth retardation. The diagnosis is readily made by identifying ova in faeces. Treatment is with mebendazole in doses of 100 mg twice daily or albendazole 400 mg daily for 3 days for patients with light infections, and for 5–7 days for those with heavy infections.

Tissue-dwelling human nematodes

Filarial worms are tissue-dwelling nematodes. The larval stages are inoculated by biting mosquitoes or flies, each specific to a particular filarial species. The larvae develop into adult worms (2–50 cm long), which, after mating, produce millions of microfilariae (170–320 μm long) that migrate in blood or skin. The life cycle is completed when the vector takes up microfilariae by biting humans. In the insect, ingested microfilariae develop into infective larvae for inoculation in humans, normally the only host.

Disease is due to the host’s immune response to the worms (both adult and microfilariae), particularly dying worms, and its pattern and severity vary with the site and stage of each species (Box 11.60). The worms are long-lived: microfilariae survive 2–3 years and adult worms 10–15 years. The infections are chronic and worst in individuals constantly reinfected.

Lymphatic filariasis

The filarial worms Wuchereria bancrofti and Brugia malayi infect approximately 120 million people globally and cause clinical outcomes ranging from subclinical infection to hydrocele and elephantiasis.

W. bancrofti is usually transmitted by night-biting culicine or anopheline mosquitoes (Fig. 11.50). The adult worms, 4–10 cm in length, live in the lymphatics, and the females produce microfilariae that circulate in large numbers in the peripheral blood, usually at night. The infection is widespread in tropical Africa, on the North African coast, in coastal areas of Asia, Indonesia and northern Australia, the South Pacific islands, the West Indies and also in North and South America.
of the lymphatic system. Silicates absorbed from volcanic soil can also cause non-filarial elephantiasis. Tropical pulmonary eosinophilia is a complication, seen mainly in India, due to microfilariae trapped in the pulmonary capillaries that are destroyed by allergic inflammation. Patients present with paroxysmal cough, wheeze and fever. If untreated, this may progress to debilitating chronic interstitial lung disease.

**Investigations**

In the earliest stages of lymphangitis, the diagnosis is made on clinical grounds, supported by eosinophilia and sometimes by positive filarial serology. Filarial infections cause the highest eosinophil counts of all helminthic infections. Microfilariae can be found in the peripheral blood at night, and either are seen moving in a wet blood film or are detected by microfiltration of a sample of lysed blood. They are usually present in hydrocele fluid, which may occasionally yield an adult filaria. By the time elephantiasis develops, microfilariae become difficult to find. Calcified filariae may sometimes be demonstrable by radiography. Movement of adult worms can be seen on scrotal ultrasound. PCR-based tests for detection of *W. bancrofti* and *B. malayi* DNA from blood have been developed.

Indirect fluorescence and ELISA detect antibodies in over 95% of active cases and 70% of established elephantiasis. The test becomes negative 1–2 years after cure. Serological tests cannot distinguish the different filarial infections. Highly sensitive and specific, commercially available, immunochromatographic card tests detect circulating *W. bancrofti* antigen using fingerprick blood samples taken at any time of the day.

In tropical pulmonary eosinophilia, serology is strongly positive and IgE levels are massively elevated but circulating microfilariae are not found. The chest X-ray shows miliary changes or mottled opacities. Pulmonary function tests show a restrictive picture.

**Management**

Treatment is aimed at halting and reversing disease progression. Diethylcarbamazine (DEC, 2 mg/kg orally 3 times daily for 12 days, or 6 mg/kg as a single dose) kills microfilariae and adult worms. Most adverse effects seen with DEC treatment are due to the host response to dying microfilariae, which is directly proportional to the microfilarial load. The main symptoms are fever, headache, nausea, vomiting, arthralgia and prostration. These usually occur within 24–36 hours of the first dose of DEC. Antihistamines or glucocorticoids treat these allergic phenomena. Combining albendazole (400 mg) with ivermectin (200 μg/kg) in a single dose, with or without DEC (300 mg), is also highly effective in clearing the parasites. Treatment of Wolbachia with doxycycline (200 mg/day) for 4–8 weeks provides additional benefit by eliminating the bacteria; this leads to interruption of parasite embryogenesis. For tropical pulmonary eosinophilia, DEC for 14 days is the treatment of choice.

**Chronic lymphatic pathology**

Experience in India and Brazil shows that active management of chronic lymphatic pathology can alleviate symptoms. Patients should be taught meticulous skin care of their lymphoedematous limbs to prevent secondary bacterial and fungal infections. Tight bandaging, massage and bed rest with elevation of the affected limb help to control the lymphoedema. Prompt diagnosis and antibiotic therapy of bacterial cellulitis prevent further lymphatic damage and worsening of existing elephantiasis. Plastic surgery may be indicated in established elephantiasis. Relief can be obtained by removal of excess tissue but recurrences are probable.

---

*B. malayi* usually causes less severe disease than *W. bancrofti* and is transmitted by *Mansonia* or *Anopheles* mosquitoes in Indonesia, Borneo, Malaysia, Vietnam, South China, South India and Sri Lanka.

**Pathology**

Several factors contribute to the pathogenesis of lymphatic filariasis. Toxins released by adult worms cause lymphangiectasia; this dilatation of the lymphatic vessels leads to lymphatic dysfunction and the chronic clinical manifestations of lymphatic filariasis, lymphoedema and hydrocele. Death of the adult worm results in acute filarial lymphangitis. The filariae are symbiotically infected with rickettsia-like bacteria (*Wolbachia* spp.), and lipopolysaccharide released from *Wolbachia* triggers inflammation. Lymphatic obstruction persists after death of the adult worm. Secondary bacterial infections cause tissue destruction. The host response to microfilariae is central to the pathogenesis of tropical pulmonary eosinophilia.

**Clinical features**

Acute filarial lymphangitis presents with fever, pain, tenderness and erythema along the course of inflamed lymphatic vessels. Inflammation of the spermatic cord, epididymis and testis is common. Episodes last a few days but may recur several times a year. Temporary oedema becomes more persistent and regional lymph nodes enlarge. Progressive enlargement, coarsening, corrugation, fissuring and bacterial infection of the skin and subcutaneous tissue develop gradually, causing irreversible ‘elephantiasis’. The scrotum may reach an enormous size. Chyluria and chylous effusions are milky and opalescent; on standing, fat globules rise to the top.

Acute lymphatic manifestations of filariasis must be differentiated from thrombophlebitis and infection. Oedema and lymphatic obstructive changes must be distinguished from congestive cardiac failure, malignancy, trauma and idiopathic abnormalities

---

**Fig. 11.50 Wuchereria bancrofti and Brugia malayi.** Life cycle of organisms and pathogenesis of lymphatic filariasis.
unless new lymphatic drainage is established. Hydroceles and chyluria can be repaired surgically.

Prevention
Treatment of the whole population in endemic areas with annual single-dose DEC (6 mg/kg), either alone or in combination with albendazole or ivermectin, can reduce filarial transmission. Mass treatment should be combined with mosquito control programmes.

Loiasis
Loiasis is caused by infection with the filaria Loa loa. The disease is endemic in forested and swampy parts of Western and Central Africa. The adult worms, 3–7 cm × 4 mm, chiefly parasitise the subcutaneous tissue of humans, releasing larval microfilariae into the peripheral blood in the daytime. The vector is Chrysops, a forest-dwelling, day-biting fly.

The host response to Loa loa is usually absent or mild, so that the infection may be harmless. From time to time a short-lived, inflammatory, oedematous swelling (a Calabar swelling) is produced around an adult worm. Heavy infections, especially when treated, may cause encephalitis.

Clinical features
The infection is often symptomless. The incubation period is commonly over a year but may be just 3 months. The first sign is usually a Calabar swelling: an irritating, tense, localised swelling that may be painful, especially if it is near a joint. The swelling is generally on a limb; it measures a few centimetres in diameter but may be diffuse and extensive. It usually disappears after a few days but may persist for 2–3 weeks. Several swellings may appear at irregular intervals, often in adjacent sites. Sometimes, there is urticaria and pruritus elsewhere. Occasionally, a worm may be seen wriggling under the skin, especially that of an eyelid, and may cross the eye under the conjunctiva, taking many minutes to do so.

Investigations
Diagnosis is by demonstrating microfilariae in blood taken during the day, but they may not always be found in patients with Calabar swellings. Antifilarial antibodies are positive in 95% of patients and there is massive eosinophilia. Occasionally, a calcified worm may be seen on X-ray.

Management
DEC (see above) is curative, in a dose of 9–12 mg/kg daily, continued for 21 days. Treatment may precipitate a severe reaction in patients with a heavy microfilaraemia, characterised by fever, joint and muscle pain, and encephalitis; microfilaraemic patients should be given glucocorticoid cover.

Prevention
Building houses away from trees and having dwellings wire-screened reduce infections. Protective clothing and insect repellents are also useful. DEC in a dose of 5 mg/kg daily for 3 days each month is partially protective.

Onchocerciasis (river blindness)
Onchocerciasis results from infection by the filarial Onchocerca volvulus. The infection is conveyed by flies of the genus Simulium, a forest-dwelling, day-biting fly. After inoculation of larvae by a bite, the worms mature in 2–4 months and live for up to 17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms, which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female O. volvulus, move actively in these nodules and in the adjacent tissues. The microfilariae are widely distributed in the skin and may invade the eye. Live microfilariae elicit little tissue reaction but dead ones may cause severe allergic inflammation, leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

Pathology
After inoculation of larvae by a bite, the worms mature in 2–4 months and live for up to 17 years in subcutaneous and connective tissues. At sites of trauma, over bony prominences and around joints, fibrosis may form nodules around adult worms, which otherwise cause no direct damage. Innumerable microfilariae, discharged by the female O. volvulus, move actively in these nodules and in the adjacent tissues. The microfilariae are widely distributed in the skin and may invade the eye. Live microfilariae elicit little tissue reaction but dead ones may cause severe allergic inflammation, leading to hyaline necrosis and loss of collagen and elastin. Death of microfilariae in the eye causes inflammation and may lead to blindness.

Clinical features
The infection may remain symptomless for months or years. The first symptom is usually itching, localised to one quadrant of the body and later becoming generalised and involving the eyes. Transient oedema of part or all of a limb is an early sign, followed by papular urticaria spreading gradually from the site of infection. This is difficult to see on dark skins, in which the most common signs are papules excoriated by scratching, spotty hyperpigmentation from resolving inflammation, and chronic changes of a rough, thickened or inelastic, wrinkled skin. Both infected and uninfected superficial lymph nodes enlarge and may hang down in folds of loose skin in the groin. Hydrocele, femoral hernias and scrotal elephantiasis can occur. Firm subcutaneous nodules of more than 1 cm in diameter (onchocercomas) occur in chronic infection.
Eye disease is most common in highly endemic areas and is associated with chronic heavy infections and nodules on the head. Early manifestations include itching, laceration and conjunctival injection. These cause conjunctivitis; sclerosing keratitis with pannus formation; uveitis, which may lead to glaucoma and cataract; and, less commonly, choroiditis and optic neuritis. Classically, ‘snowflake’ deposits are seen in the edges of the cornea.

**Investigations**

The finding of nodules or characteristic lesions of the skin or eyes in a patient from an endemic area, associated with eosinophilia, is suggestive. Skin snips or shavings, taken with a conoesceral punch or scalpel blade from calf, buttock and shoulder, are placed in saline under a cover slip on a microscope slide and examined after 4 hours. Microfilariae are seen wriggling free in all but the lightest infections. Slit-lamp examination may reveal microfilariae moving in the anterior chamber of the eye or trapped in the cornea. A nodule may be removed and incised, showing the coiled, thread-like adult worm.

Filarial antibodies are positive in up to 95% of patients. Rapid strip tests to detect antibody or antigen are under clinical evaluation. When there is a strong suspicion of onchocerciasis but tests are negative, a provocative Mazzotti test, in which administration of 0.5–1.0 mg/kg of DEC exacerbates pruritus or dermatitis, strongly suggests onchocerciasis.

**Management**

Ivermectin is recommended, in a single dose of 100–200 μg/kg, repeated several times at 3-monthly intervals to prevent relapses. It kills microfilariae and has minimal toxicity. In the rare event of a severe reaction causing oedema or postural hypotension, prednisolone 20–30 mg may be given daily for 2 or 3 days. Ivermectin has little macrofilaricidal effect so that, 1 year after ivermectin treatment, skin microfilarial densities regain at least 20% of pre-treatment levels; repeated treatments are required for the lifespan of the adult worm. Eradication of Wolbachia with doxycycline (100 mg daily for 6 weeks) prevents worm reproduction.

**Prevention**

Mass treatment with ivermectin reduces community morbidity and slows the progression of eye disease but does not clear worm infection. *Simulium* can be destroyed in its larval stage by the application of insecticide to streams. Long trousers, skirts and sleeves discourage the fly from biting.

### Dracunculiasis (Guinea worm)

Infestation with the Guinea worm *Dracunculus medinensis* manifests when the female worm, over a metre long, emerges from the skin. Humans are infected by ingesting a small crustacean, *Cyclops*, which inhabits wells and ponds, and contains the infective larval stage of the worm. The worm was widely distributed across Africa and the Middle East but successful global eradication programmes have limited the infection to a few countries in sub-Saharan Africa. However, recent findings of dog dracunculiasis in Chad and Ethiopia pose a new threat to eradication efforts.

**Management and prevention**

Traditionally, the protruding worm is extracted by winding it out gently over several days on a matchstick. The worm must never be broken. Antibiotics for secondary infection and prophylaxis of tetanus are also required.

A global eradication campaign aims to provide clean drinking water and eradicate water fleas from drinking water by simple filtration of water through a plastic mesh filter and chemical treatment of water supplies.

### Other filariases

**Mansonella perstans**

This filarial worm is transmitted by the midges *Culicoides austeni* and *C. grahami*. It is common throughout equatorial Africa, as far south as Zambia, and also in Trinidad and parts of northern and eastern South America.

* M. perstans has never been proven to cause disease but it may be responsible for a persistent eosinophilia and occasional allergic manifestations. *M. perstans* is resistant to ivermectin and DEC, and the infection may persist for many years.

**Dirofilaria immitis**

This dog heartworm infects humans, causing skin and lung lesions. It is not uncommon in the USA, Japan and Australia.

### Zoonotic nematodes

**Trichinosis (trichinellosis)**

*Trichinella spiralis* is a nematode that parasitises rats and pigs, and is transmitted to humans by ingestion of partially cooked infected pork, particularly sausage or ham, or occasionally by bear meat. Symptoms result from invasion of intestinal submucosa by ingested larvae, which develop into adult worms, and the secondary invasion of striated muscle by fresh larvae produced by these adult worms. Outbreaks have occurred in countries where pork is eaten.

**Clinical features**

The clinical features of trichinosis are determined by the larval numbers. A light infection with a few worms may be asymptomatic; a heavy infection causes nausea and diarrhoea 24–48 hours after the infected meal. A few days later, the symptoms associated with larval invasion predominate: there is fever and oedema of the face, eyelids and conjunctivae; invasion of the diaphragm may cause pain, cough and dyspnoea; and involvement of the muscles of the limbs, chest and mouth causes stiffness, pain and tenderness in affected muscles. Larval migration may cause acute myocarditis and encephalitis. Eosinophilia is observed after the second week. An intense infection may prove fatal but those who survive recover completely.

**Investigations**

Frequently, people who have eaten infected pork from a common source develop symptoms at about the same time. Biopsy from the deltoid or gastrocnemius muscle after the third week of symptoms may reveal encysted larvae. Serological tests are also helpful.

**Management**

Treatment is with albendazole (400 mg twice daily for 8–14 days) or mebendazole (200–400 mg three times daily for 3 days, followed by 400–500 mg three times daily for 10 days). Treatment commenced early in infection kills newly formed adult worms in the submucosa and reduces the number of larvae reaching the...
muscles. Glucocorticoids are necessary to control the serious effects of acute inflammation.

### Anisakiasis (herring worm)

This infection is caused by the larvae of a fish nematode (*Anisakis simplex* or *Pseudoterranova decipiens*) and is associated with consumption of under-cooked fish or squid. The parasite cannot complete its life cycle in humans but larval ingestion is associated with pharyngeal tingling, abdominal pain, diarrhoea and vomiting. Diagnosis is made by identification of the larva by patients or endoscopists, and albendazole (400 mg twice a day for 5 days) can be used in treatment if larvae are not removed.

### Cutaneous larva migrans

Cutaneous larva migrans (CLM) is the most common linear lesion seen in travellers (Fig. 11.52). Intensely pruritic, linear, serpiginous lesions result from the larval migration of the dog hookworm (*Ancylostoma caninum*). The track moves across the skin at a rate of 2–3 cm/day. This contrasts with the fast-moving transient rash of *Strongyloides* (p. 289). Although the larvae of dog hookworms frequently infect humans, they do not usually develop into the adult form. The most common site for CLM is the foot but elbows, breasts and buttocks may be affected. Most patients with CLM have recently visited a beach where the affected part was exposed. The diagnosis is clinical. Treatment may be local with 12-hourly application of 15% thiabendazole cream, or systemic with a single dose of albendazole (400 mg) or ivermectin (150–200 μg/kg).

### Angiostrongylus cantonensis

The rat lungworm infects humans in Asia and the Pacific basin, via infected snails or contaminated water. It causes eosinophilic meningitis. The role of combination therapy with glucocorticoids and albendazole remains controversial.

### Gnathostomiasis

Gnathostomiasis is a nematode infection that occurs predominantly in South-east Asia and is due to *Gnathostoma spinigerum*. It also occurs in other parts of Asia, Central and South America, and Africa. Humans are infected by the larvae from intermediate hosts (raw or under-cooked freshwater fish, shrimps and frogs) and are not definitive hosts, so the life cycle is incomplete. Pruritic, painful, migratory nodules appear 3–4 weeks after ingestion due to larval migration. Complications include cough, visual disturbance, eosinophilic meningitis or encephalitis. Serology confirms diagnosis and the preferred treatment is albendazole (400 mg twice daily) for 21 days, but its role in visual or neurological disease is uncertain as it may increase larval migration.

### Treantodes (flukes)

These leaf-shaped worms are parasitic to humans and animals. Their complex life cycles may involve one or more intermediate hosts, often freshwater molluscs.

### Schistosomiasis

Schistosomiasis is a major cause of morbidity in the tropics. The species commonly causing disease in humans are: *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *S. mekongi* and *S. intercalatum*. *S. haematobium* is sometimes called bilharzia or bilharziasis. Schistosome eggs have been found in Egyptian mummies.

The life cycle is shown in Figure 11.53A. The ovum is passed in the urine or faeces of infected individuals and gains access to fresh water, where the ciliated miracidium inside it is liberated; it enters its intermediate host, a species of freshwater snail, and multiplies. Large numbers of fork-tailed cercariae are then liberated into the water, where they may survive for 2–3 days. Cercariae can penetrate the skin or the mucous membrane of the mouth of humans. They transform into schistosomulae and moult as they pass through the lungs; then they are carried by the blood stream to the liver, and so to the portal vein. Those of *S. haematobium* may leave the liver. The most serious, although rare, site of ectopic egg deposition is the CNS. Egg deposition in the pulmonary vasculature, and the resultant host response, can lead to pulmonary hypertension.

Infections caused by helminths

Clinical features

Recent travellers, especially those overlanding through Africa, may present with allergic manifestations and eosinophilia; residents of schistosomiasis-endemic areas are more likely to present with chronic urinary tract pathology or portal hypertension.

During the early stages of infection, there may be itching lasting 1–2 days at the site of cercarial penetration (‘swimmer’s itch’). After a symptom-free period of 3–5 weeks, acute schistosomiasis (Katayama syndrome) may present with allergic manifestations, such as urticaria, fever, muscle aches, abdominal pain, headaches, cough and sweating. On examination, hepatomegaly, splenomegaly, lymphadenopathy and pneumonia may be present. These allergic phenomena may be severe in infections with *S. mansoni* and *S. japonicum*, but are rare with *S. haematobium*. The features subside after 1–2 weeks.

Chronic schistosomiasis is due to egg deposition and occurs months to years after infection. The symptoms and signs depend on the intensity of infection and the species of infecting schistosome (Box 11.61).

**Schistosoma haematobium**

Humans are the only natural hosts of *S. haematobium*, which is highly endemic in Egypt and East Africa, and occurs throughout Africa and the Middle East (Fig. 11.54). Infection can be acquired after a brief exposure, such as swimming in freshwater lakes in Africa.

Painless terminal haematuria is usually the first and most common symptom. Frequency of micturition follows, due to bladder neck obstruction. Later, frequent urinary tract infections, bladder or ureteric stones, hydropnephrosis, and ultimately renal failure with a contracted calcified bladder may occur. Pain is often felt in the iliac fossa or in the loin, and radiates to the groin. In several endemic areas, there is a strong epidemiological association of *S. haematobium* infection with squamous cell carcinoma of the bladder. Disease of the seminal vesicles may lead to haematospermia. Females may develop schistosomal papillomas of the vulva, and schistosomal lesions of the cervix may be mistaken for cancer. Intestinal symptoms may follow...
Involvement of the bowel wall. Ectopic worms cause skin or spinal cord lesions.

The severity of *S. haematobium* infection varies greatly and many with a light infection are asymptomatic. However, as adult worms can live for 20 years or more and lesions may progress, these patients should always be treated.

**Schistosoma mansoni**

*S. mansoni* is endemic throughout Africa, the Middle East, Venezuela, Brazil and the Caribbean (Fig. 11.54).

Characteristic symptoms begin 2 months or more after infection. They may be slight – no more than malaise – or consist of abdominal pain and frequent stools that contain blood-stained mucus. With severe advanced disease, increased discomfort from rectal polyps may be experienced. The early hepatomegaly is reversible but portal hypertension may cause massive splenomegaly, fatal haematemesis from oesophageal varices, or progressive ascites (p. 869). Liver function is initially preserved because the pathology is fibrotic rather than cirrhotic.

**Schistosoma japonicum, S. mekongi and S. intercalatum**

In addition to humans, the adult worm of *S. japonicum* infects the dog, rat, field mouse, water buffalo, ox, cat, pig, horse and sheep. Although other *Schistosoma* spp. can infect species other than humans, the non-human reservoir seems to be particularly important only in transmission for *S. japonicum*. *S. japonicum* is prevalent in the Yellow River and Yangtze–Jiang basins in China, where the infection is a major public health problem. It also has a focal distribution in the Philippines, Indonesia and Thailand (Fig. 11.54). The related *S. mekongi* occurs in Laos, Thailand and Myanmar, and *S. intercalatum* in West and Central Africa.

The pathology of *S. japonicum* is similar to that of *S. mansoni*, but as this worm produces more eggs, the lesions tend to be more extensive and widespread. The clinical features resemble those of severe infection with *S. mansoni*, with added neurological features. The small and large bowel may be affected, and hepatic fibrosis with splenic enlargement is usual. Deposition of eggs or worms in the CNS, especially in the brain or spinal cord, causes symptoms in about 5% of infections, notably epilepsy, blindness, hemiplegia or paraplegia.

**Investigations**

There is marked eosinophilia. Serological tests (ELISA) are useful as screening tests but remain positive after treatment.

In *S. haematobium* infection, dipstick urine testing shows blood and albumin. The eggs can be found by microscopic examination of the centrifuged deposit of terminal stream urine (Fig. 11.55). Ultrasound assesses the urinary tract; bladder wall thickening, hydronephrosis and bladder calcification can be detected. Cystoscopy reveals ‘sandy’ patches, bleeding mucosa and later distortion.

In a heavy infection with *S. mansoni* or *S. japonicum*, the characteristic egg with its lateral spine can usually be found in the stool. When the infection is light or of long duration, a rectal biopsy can be examined. Sigmoidoscopy may show inflammation or bleeding. Biopsies should be examined for ova.

**Management**

The object of therapy is to kill the adult schistosomes and stop egg-laying. Praziquantel (20 mg/kg orally twice daily for 1 day) is the drug of choice for all forms of schistosomiasis except *S. japonicum* and *S. mekongi*, for which 60 mg/kg (20 mg for 3 doses) is recommended. The drug produces parasitological cure in 80% of treated individuals and over 90% reduction in egg counts in the remainder. Side-effects are uncommon but include nausea and abdominal pain. Praziquantel therapy in early infection reverses hepatomegaly, bladder wall thickening and granulomas.

Surgery may be required to deal with residual lesions such as ureteric stricture, small fibrotic urinary bladders, or granulomatous masses in the brain or spinal cord. Removal of rectal papillomas by diathermy or by other means may provide symptomatic relief.

**Prevention**

No single means of controlling schistosomiasis has been established to date. The life cycle is terminated if fresh water containing the snail host is not contaminated by ova-containing urine or faeces. The provision of latrines and of a safe water supply, however, remains a major problem in rural areas throughout the world.

*In the UK, available from the Hospital for Tropical Diseases, London.

Tropics. Furthermore, S. japonicum has so many hosts besides humans that latrines would have little impact. Population mass treatment annually helps prevent S. haematobium and S. mansoni infection but so far has had little success with S. japonicum. Targeting the intermediate host, the snail, is problematic and has not, on its own, proved successful. For personal protection, contact with infected water must be avoided.

Liver flukes

Liver flukes infect at least 20 million people and remain an important public health problem in endemic areas. They are associated with abdominal pain, hepatomegaly and relapsing cholangitis. Clonorchis sinensis and Opisthorchis felineus are major aetiological agents of bile duct cancer. The three major liver flukes have similar life cycles and pathologies, as outlined in Box 11.62.

Other flukes of medical importance include lung and intestinal flukes (see Box 11.58).

Cestodes (tapeworms)

Cestodes are ribbon-shaped worms that inhabit the intestinal tract. They have no alimentary system and absorb nutrients through the tegumental surface. The anterior end, or scolex, has suckers for attaching to the host. From the scolex, a series of progressively developing segments arise, the proglottides, which may continue to show active movements when shed. Cross-fertilisation takes place between segments. Ova, present in large numbers in mature proglottides, remain viable for weeks, and during this period they may be consumed by the intermediate host. Larvae liberated from the ingested ova pass into the tissues of the intermediate host, forming larval cysticerci.

Tapeworms cause two distinct patterns of disease: either intestinal infection or systemic cysticercosis (Fig. 11.56). Taenia saginata (beef tapeworm), Taenia asiatica and Diphyllobothrium latum (fish tapeworm) cause only intestinal infection in humans, following ingestion of intermediate hosts. Taenia solium causes intestinal infection if a cysticerci-containing intermediate host is ingested, and cysticercosis (systemic infection from larval migration) if ova are ingested. Echinococcus granulosus (dog tapeworm) does not cause human intestinal infection, but causes hydatid disease (which is analogous to cysticercosis) following ingestion of ova and subsequent larval migration.
Humans acquire tapeworm by eating under-cooked beef infected with the larval stage of *T. saginata*, under-cooked pork containing the larval stage of *T. solium* or *T. asiatica*, or under-cooked freshwater fish containing larvae of *D. latum*. Usually, only one adult tapeworm is present in the gut but up to 10 have been reported. The ova of all the three *Taenia* are indistinguishable microscopically. However, examination of scolex and proglottides can differentiate them: *T. solium* has a rostellum and two rows of hooklets on the scolex, and discharges multiple proglottides (3–5) attached together with lower degrees of uterine branching (approximately 10); *T. saginata* has only four suckers in its scolex, and discharges single proglottids with greater uterine branching (up to 30); *T. asiatica* has a rostellum without hooks on its scolex and is difficult to differentiate from *T. saginata*, except that there are fewer uterine branches (16–21).

**Taenia solium**
*T. solium*, the pork tapeworm, is common in central Europe, South Africa, South America and parts of Asia. It is not as large as *T. saginata*. The adult worm is found only in humans following the ingestion of pork containing cysticerci. Intestinal infection is treated with praziquantel (5–10 mg/kg) or niclosamide (2 g), both as a single dose, or alternatively with nitazoxanide (500 mg twice daily for 3 days). These are followed by a mild laxative (after 1–2 hours) to prevent retrograde intestinal autoinfection. Cooking pork well prevents intestinal infection. Great care must be taken while attending a patient harbouring an adult worm to avoid ingestion of ova or segments.

**Taenia saginata**
Infection with *T. saginata* occurs in all parts of the world. The adult worm may be several metres long and produces little or no intestinal upset in human beings, but identification of segments in the faeces or on underclothing may distress the patient. Ova may be found in the stool. Praziquantel is the drug of choice; niclosamide or nitazoxanide is an alternative. Prevention depends on efficient meat inspection and the thorough cooking of beef.

**Taenia asiatica**
*T. asiatica* is a newly recognised species of *Taenia*, restricted to Asia. It is acquired by eating uncooked meat or viscera of pigs. Clinical features and treatment are similar to those of *T. saginata*.

**Cysticercosis**
Human cysticercosis is acquired by ingesting *T. solium* tapeworm ova, from either contaminated fingers or food (Fig. 11.56). The larvae are liberated from eggs in the stomach, penetrate the intestinal mucosa and are carried to many parts of the body, where they develop and form cisticerci. 0.5–1 cm cysts that contain the head of a young worm. They do not grow further or migrate. Common locations are the subcutaneous tissue, skeletal muscles and brain (Fig. 11.57).

**Clinical features**
Superficial cysts can be palpated under the skin or mucosa as pea-like ovoid bodies, but cause few or no symptoms and will eventually die and become calcified.

**Fig. 11.57 Neurocysticercosis.** T2-weighted axial image of the brain showing multiple lesions of neurocysticercosis (large arrows show the largest lesions).

Heavy brain infections, especially in children, may cause features of encephalitis. More commonly, however, cerebral signs do not occur until the larvae die, 5–20 years later. Epilepsy, including new-onset focal seizures, personality changes, staggering gait and signs of hydrocephalus are the most common features.

**Investigations**
Calcified cysts in muscles can be recognised radiologically. In the brain, however, less calcification takes place and larvae are only occasionally visible by plain X-ray; CT or magnetic resonance imaging (MRI) will usually show them. Epileptic fits starting in adult life suggest the possibility of cysticercosis if the patient has lived in or travelled to an endemic area. The subcutaneous tissue should be palpated and any nodule excised for histology. Radiological examination of the skeletal muscles may be helpful. Antibody detection is available for serodiagnosis.

**Management and prevention**
Albendazole (15 mg/kg daily for a minimum of 8 days) has now become the drug of choice for parenchymal neurocysticercosis. Praziquantel (50 mg/kg in 3 divided doses daily for 10 days) is another option. Prednisolone (10 mg 3 times daily) is also given for 14 days, starting 1 day before the albendazole or praziquantel. In addition, antiepileptic drugs should be given until the reaction in the brain has subsided. Operative intervention is indicated for hydrocephalus. Studies from India and Peru suggest that most small, solitary cerebral cysts will resolve without treatment.

**Echinococcus granulosus (Taenia echinococcus) and hydatid disease**
Dogs are the definitive hosts of the tiny tapeworm *E. granulosus*. The larval stage, a hydatid cyst, normally occurs in sheep, cattle,
Ectoparasites

Management and prevention

Hydatid cysts should be excised wherever possible. Great care is taken to avoid spillage and cavities are sterilised with 0.5% silver nitrate or 2.7% sodium chloride. Albendazole (400 mg twice daily for 3 months) should also be used and is often combined with PAIR (percutaneous puncture, aspiration, injection of scolicidal agent and re-aspiration). Praziquantel (20 mg/kg twice daily for 14 days) also kills protoscolices perioperatively.

Prevention is difficult when there is a close association with dogs. Personal hygiene, satisfactory disposal of carcasses, meat inspection and deworming of dogs reduces the prevalence of disease.

Other tapeworms

Other cestodes’ adult or larval stages may infect humans. Sparganosis is a condition in which an immature worm develops in humans, usually subcutaneously, as a result of eating or applying to the skin the secondary or tertiary intermediate host, such as frogs or snakes.

Ectoparasites

Ectoparasites only interact with the outermost surfaces of the host; see also page 1241.

Jiggers (tungiasis)

This is widespread in tropical America and Africa, and is caused by the sand flea Tunga penetrans. The pregnant flea burrows into the skin around toes and produces large numbers of eggs.

Fig. 11.58 Hydatid disease. A Life cycle of Echinococcus granulosus B Daughter cysts removed at surgery C Within the daughter cysts are the protoscolices.
The burrows are intensely irritating and the whole inflammatory nodule should be removed with a sterile needle. Secondary infection of lesions is common.

**Myiasis**

Myiasis is due to skin infestation with larvae of the South American botfly, *Dermatobia hominis*, or the African tumbu fly, *Cordylobia anthropophaga*. The larvae develop in a subcutaneous space with a central sinus. This orifice is the air source for the larvae, and periodically the larval respiratory spiracles protrude through the sinus. Patients with myiasis feel movement within the larval burrow and can experience intermittent sharp, lancinating pains. Myiasis is diagnosed clinically and should be suspected with any furuncular lesion accompanied by pain and a crawling sensation in the skin. The larva may be suffocated by blocking the respiratory orifice with petroleum jelly and gently removing it with tweezers. Secondary infection of myiasis is rare and rapid healing follows removal of intact larvae.

**Fungal infections**

Fungal infections, or mycoses, are classified as superficial, subcutaneous or systemic (deep), depending on the degree of tissue invasion. They are caused by filamentous fungi (moulds), yeasts or by fungi that vary between these two forms, depending on environmental conditions (dimorphic fungi; Fig. 11.59).

### Superficial mycoses

Superficial cutaneous fungal infections caused by dermatophyte fungi are described in Chapter 29.

#### Chromoblastomycosis

Chromoblastomycosis is a predominantly tropical or subtropical disease caused by environmental dematiaceous (dark-pigmented) fungi, most commonly *Fonsecaea pedrosi*. Other causes include *F. compacta, Cladophialophora carrionii* and *Phialophora verrucosa*. The disease is a cutaneous/subcutaneous mycosis acquired by traumatic inoculation. Commonly affected areas

#### Candidiasis (thrush)

Superficial candidiasis is caused by *Candida* spp., mainly *C. albicans*. Manifestations include oropharyngeal (pp. 790 and 1240) and vaginal candidiasis (‘thrush’), intertrigo and chronic paronychia. Superficial candidiasis often follows antibiotic therapy. Intertrigo is characterised by inflammation in skin folds with surrounding ‘satellite lesions’. Chronic paronychia is associated with frequent wetting of the hands. Superficial candidiasis is treated mainly with topical azoles (p. 126), oral azoles being reserved for refractory or recurrent disease. Severe oropharyngeal and oesophageal candidiasis is a consequence of CD4+ T-lymphocyte depletion/dysfunction, as in HIV infection (p. 316). Recurrent vaginal or penile candidiasis may be a manifestation of diabetes mellitus. Rarely, mutations in the autoimmune regulator gene (*AIRE*) or signal transducer and activator of transcription 1 (*STAT1*) cause a syndrome of chronic mucocutaneous candidiasis (p. 689). This is characterised by *Candida* infections of skin, mucosa and nails, with hyperkeratotic nails and erythematous periungual skin. Patients have cell-mediated immune defects against *Candida* and may have polyendocrinopathy and autoimmune features.

#### Subcutaneous mycoses

#### Filamentous fungi (moulds)

Characterised by the production of elongated, cylindrical, often septate cells (hyphae) and conidia (spores)

Examples:
- *Aspergillus* spp. (*A. fumigatus* shown here)
- *Fusarium* spp.
- Dermatophyte fungi (*Tricophyton* spp., *Microsporum* spp. etc.)
- Mucorales

#### Dimorphic fungi

Exist in filamentous (top) or yeast (bottom) form, depending on environmental conditions

Examples:
- *Histoplasma capsulatum*, *Coccidioides immitis*, *Paracoccidioides brasiliensis* (shown here), *Blastomyces dermatitidis*
- *Sporothrix schenckii*
- *Talaromyces marneffei*
- *Malassezia* spp.

#### Yeasts

Characterised by the production of oval or round cells, which reproduce by binary fission (budding)

Examples:
- *Candida* spp.*
- *Cryptococcus* spp. (*C. neoformans* shown here)

---

Fig. 11.59 Classification of medically important fungi. Fungal classification is based on simple morphological characteristics. *Pneumocystis jirovecii* is morphologically distinct from other fungi and does not fit into this classification. Although *Candida albicans* exists in a number of forms, including filamentous (hyphae and pseudohyphae), it is generally encountered in its yeast form so is classified in this category. Insets (dimorphic fungi) Courtesy of Beatriz Gomez and Angela Restrepo, CIB, Medellin, Colombia.
include the foot, ankle and lower leg. Lesions may start several months after the initial injury, and medical attention is often sought several years later. The initial lesion is a papule. Further papules develop and coalesce to form irregular plaques. Nodular lesions may produce a characteristic ‘cauliflower’ appearance.

Diagnosis is by histopathological examination of infected material, which shows dematiaceous, rounded, thick-walled ‘sclerotic bodies’ with septa at right angles to each other. The aetiological agent is confirmed by culture. Therapeutic approaches include antifungal agents, cryosurgery and surgical excision, alone or in combination, but the optimal therapy is unknown. Itraconazole and terbinafine are the most effective antifungal agents. However, posaconazole has also been used with a good outcome.

**Mycetoma (eumycetoma and actinomycetoma)**

Mycetoma is a chronic suppurative infection of the deep soft tissues and bones, most commonly of the limbs but also of the abdominal or chest wall or head. It is caused by either filamentous fungi, Eumycetes (eumycetoma – 40%) or aerobic Actinomycetes (actinomycetoma – 60%). Many fungi cause eumycetomas, the most common being *Madurella mycetomatis*, *M. grisea*, *Leptosphaeria senegalensis* and *Scedosporium apiospermum*; causes of actinomycetoma include *Nocardia*, *Streptomyces* and *Actinomadura* spp. Both groups produce characteristically coloured ‘grains’ (microcolonies), the colour depending on the organism (black grains – eumycetoma, red and yellow grains – actinomycetoma, white grains – either). The disease occurs mostly in the tropics and sub-tropics.

**Clinical features**

The disease is acquired by inoculation (e.g., from a thorn) and most commonly affects the foot (Madura foot). Mycetoma begins as a painless swelling at the implantation site, which becomes chronic and progressive, grows and spreads steadily within the soft tissues, eventually extending into bone. Nodules develop under the epidermis and these rupture, revealing sinuses through which grains may be discharged. Sinuses heal with scarring, while fresh sinuses appear elsewhere. Deeper tissue invasion and bone involvement are less rapid and extensive in eumycetoma than actinomycetoma. There is little pain and usually no fever or lymphadenopathy, but there is progressive disability.

**Investigations**

Diagnosis of mycetoma involves identification of grains in pus, and/or histopathological examination of tissue. Culture is necessary for species identification and susceptibility testing. Serological tests are not available.

**Management**

Eumycetoma is usually treated with a combination of surgery and antifungal therapy. Antifungal susceptibility testing, if available, is recommended, although clinical outcome does not necessarily correspond to in vitro test results. Itraconazole and ketoconazole (both 200–400 mg/day) are used most commonly. Success has also been reported with terbinafine monotherapy, and refractory cases have responded to voriconazole or posaconazole. Amphotericin B is not usually effective. Therapy is continued for 6–12 months or longer. In extreme cases, amputation may be required. Actinomycetoma is treated with prolonged antibiotic combinations, most commonly streptomycin and dapsone. Dapsone is replaced by co-trimoxazole in intolerance or refractory disease. Success has also been reported with co-trimoxazole plus amikacin, with rifampicin added in difficult cases and to prevent recurrence.

**Phaeohyphomycosis**

Phaeohyphomycoses are a heterogeneous group of fungal diseases caused by a large number (more than 70) of dematiaceous fungi. In phaeohyphomycosis, the tissue form of the fungus is predominantly mycelial (filamentous), as opposed to eumycetoma (grain) or chromoblastomycosis (sclerotic body). Disease may be superficial, subcutaneous or deep. The most serious manifestation is cerebral phaeohyphomycosis, which presents with a ring-enhancing, space-occupying cerebral lesion. Optimal therapy for this condition has not been established but usually consists of neurosurgical intervention and antifungal (usually triazole) therapy. Causative agents are *Cladophialophora bantiana*, *Fonsecaea* spp. and *Rhinocladiella mackenziei*, which occurs mainly in the Middle East and is usually fatal.

**Sporotrichosis**

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungal saprophyte of plants in tropical and subtropical regions. Disease is caused by dermal inoculation of the fungus, usually from a thorn (occasionally from a cat scratch). In fixed cutaneous sporotrichosis, a subcutaneous nodule develops at the site of infection and subsequently ulcerates, with a purulent discharge. The disease may then spread along the cutaneous lymphatic channels, resulting in multiple cutaneous nodules that ulcerate and discharge (lymphocutaneous sporotrichosis). Rarer forms include cutaneous disease presenting with arthritis. Later, draining sinuses may form. Pulmonary sporotrichosis occurs as a result of inhalation of the conidia (spores) and causes chronic cavitary fibronodular disease with haemoptysis and constitutional symptoms. Disseminated disease may occur, especially in patients with HIV.

**Investigations**

Typical yeast forms detected on histology confirm diagnosis but are rarely seen; the fungus can also be cultured from biopsy specimen. A latex agglutination test detects *S. schenckii* antibodies in serum.

**Management**

Cutaneous and lymphocutaneous disease is treated with itraconazole (200–400 mg daily, prescribed as the oral solution, which has better bioavailability than the capsule formulation) for 3–6 months. Alternative agents include a saturated solution of potassium iodide (SSKI, given orally), initiated with 5 drops and increased to 40–50 drops 3 times daily, or terbinafine (500 mg twice daily). Localised hyperthermia may be used in pregnancy (to avoid azole use). Osteoarticular disease requires a longer course of therapy (at least 12 months). Severe or life-threatening disease is treated with amphotericin B (lipid formulation preferred).

**Systemic mycoses**

**Aspergillosis**

Aspergillosis is an opportunistic systemic mycosis, which affects the respiratory tract predominantly. It is described on page 596.
Candidiasis

Systemic candidiasis is an opportunistic mycosis caused by Candida spp. The most common cause is C. albicans. Other agents include C. dubliniensis, C. glabrata, C. krusei, C. parapsilosis and C. tropicalis. Candida species identification often predicts susceptibility to fluconazole: C. krusei is universally resistant, many C. glabrata isolates have reduced susceptibility or are resistant, and other species are mostly susceptible. Candidiasis is usually an endogenous disease that originates from oropharyngeal, genitourinary or skin colonisation, although nosocomial spread occurs. C. auris is an emerging species, which has a particular propensity for nosocomial transmission.

Syndromes of systemic candidiasis

Acute disseminated candidiasis

This usually presents as candidaemia (isolation of Candida spp. from the blood). The main predisposing factor is the presence of a central venous catheter. Other major factors include recent abdominal surgery, total parenteral nutrition (TPN), recent antimicrobial therapy and localised Candida colonisation. Up to 40% of cases will have ophthalmic involvement, with characteristic retinal ‘cotton wool’ exudates. As this is a sight-threatening condition, candidaemic patients should have a full ophthalmoscopy review. Skin lesions (non-tender pink/red nodules) may be seen. Although predominantly a disease of intensive care and surgical patients, acute disseminated candidiasis and/or Candida endophthalmitis is seen occasionally in injection drug-users, due to candidal contamination of citric acid or lemon juice used to dissolve heroin.

Chronic disseminated candidiasis (hepatosplenic candidiasis)

Persistent fever in a neutropenic patient, despite antibacterial therapy and neutrophil recovery, associated with the development of abdominal pain, raised alkaline phosphatase and multiple lesions in abdominal organs (e.g. liver, spleen and/or kidneys) on radiological imaging, suggests a diagnosis of hepatosplenic candidiasis. This represents a form of immune reconstitution syndrome (p. 104) in patients recovering from neutropenia and usually lasts for several months, despite appropriate therapy.

Other manifestations

Renal tract candidiasis, osteomyelitis, septic arthritis, peritonitis, meningitis and endocarditis are all well recognised and are usually sequelae of acute disseminated disease. Diagnosis and treatment of these conditions require specialist mycological advice.

Management

Blood cultures positive for Candida spp. must never be ignored. Acute disseminated candidiasis is treated with antifungal therapy, removal of any in-dwelling central venous catheter (whether known to be the source of infection or not) and removal of any documented source. Candidaemia should be treated initially with an echinocandin (p. 126), with subsequent adjustment (usually to intravenous or oral fluconazole) guided by clinical response, species identification and susceptibility testing. Treatment should continue for a minimum of 14 days. Alternative therapies include voriconazole and amphotericin B formulations.

Chronic disseminated candidiasis requires prolonged treatment over several months with fluconazole or other agents, depending on species and clinical response. The duration of the condition may be reduced by adjuvant therapy with systemic glucocorticoids.

Cryptococcosis

Cryptococcosis is a systemic mycosis caused by two environmental yeast species, Cr. neoformans and Cr. gattii. Cr. neoformans is distributed worldwide and is primarily an opportunistic pathogen, most commonly associated with HIV infection (p. 321). Cr. gattii is a primary pathogen with a widespread distribution that includes Australasia, Africa, Canada (Vancouver Island) and the north-western USA.

Cryptococcosis is acquired by inhalation of yeasts. These may disseminate to any organ, most commonly the CNS and skin. The manifestations of Cr. neoformans are most severe in immunocompromised individuals. Conversely, Cr. gattii causes severe disease in immunocompetent hosts. Disseminated cryptococcosis (sepsis with cryptococci present in the blood stream or at multiple sites) is largely restricted to immunocompromised patients. CNS manifestations of cryptococcosis include meningitis (p. 321) and cryptococcoma (Fig. 11.60), the latter more likely with Cr. gattii infection. Manifestations of pulmonary cryptococcosis range from severe pneumonia (in more immunocompromised patients) to asymptomatic disease with single or multiple pulmonary nodules, sometimes exhibiting cavitation (in patients with lesser immunosuppression). Cryptococcal nodules may mimic other causes of lung pathology, such as tuberculosis or malignancy, and diagnosis requires histopathology and/or culture.

Treatment of severe cryptococcosis is the same as for cryptococcal meningitis, initially with liposomal amphotericin B (p. 321). Mild pulmonary disease is usually treated with fluconazole, although for asymptomatic nodules resection of the lesions is likely to be sufficient.

Fusariosis

Fusarium spp. cause disseminated disease in patients with prolonged neutropenia. The disease presents with...
Tender, erythematous papules/nodules on upper arm. in blood culture medium.

**Mucormycosis**

Mucormycosis is a severe but uncommon opportunistic systemic mycosis caused by a number of ‘mucoraceous’ moulds, most commonly *Mucor* spp., *Absidia* spp., *Rhizomucor* spp., *Rhizopus* spp. Disease patterns include rhinoencephalocraniumfacial, pulmonary, cutaneous and systemic disease. All are characterised by the rapid development of severe tissue necrosis, which is almost always fatal if left untreated. The most common predisposing factors are profound immunosuppression from neutropenia and/or haematopoietic stem cell transplantation, uncontrolled diabetes mellitus, iron chelation therapy with desferrioxamine and severe burns.

Definitive diagnosis is by culture but histopathological confirmation is required, as the fungi may be environmental contaminants. Treatment requires a combination of antifungal therapy and surgical débridement, with correction of predisposing factor(s) if possible. High-dose lipid-formulated amphotericin B is most commonly used. Posaconazole is active against many mucoraceous moulds in vitro and may be used as a second-line agent or as oral ‘step-down’ therapy.

**Talaromyces (formerly *Penicillium*) marneffei infection**

*T. marneffei* is a thermally dimorphic pathogen (filamentous in environmental conditions and yeast at body temperature), which causes disease in South-east Asia, mainly in association with HIV infection (although immunocompetent patients may also be infected). Acquisition is usually by inhalation of environmental spores, with primary lung infection followed by haematogenous dissemination. A generalised papular rash, which progresses to widespread necrosis and ulceration, is a characteristic feature. Skin lesions may resemble molluscum contagiosum. Diagnosis is by histopathology and/or culture of respiratory secretions, blood or any infected clinical material (e.g. skin lesions, bone marrow, biopsies). Treatment involves an amphotericin B formulation followed by itraconazole (in severe infection), or itraconazole alone.

**Histoplasmosis**

Histoplasmosis is a primary systemic mycosis caused by the dimorphic fungus *Histoplasma capsulatum*. *H. capsulatum* var. *capsulatum* is endemic to east-central USA (especially the Mississippi and Ohio river valleys), parts of Canada, Latin America, the Caribbean, East and South-east Asia, and Africa. It occurs sporadically in Australia and India, and is very rare in Europe. *H. capsulatum* var. *duboisii* is found in West Africa and Madagascar.

The primary reservoir of *H. capsulatum* is soil enriched by bird and bat droppings, in which the fungus remains viable for many years. Infection is by inhalation of infected dust. Natural infections are found in bats, which represent a secondary reservoir of infection. Histoplasmosis is a specific hazard for explorers of caves and people who clear out bird (including chicken) roosts.

**Pathology**

The organism is inhaled in the form of conidia or hyphal fragments and transforms to the yeast phase during infection. Conidia or yeasts are phagocytosed by alveolar macrophages and neutrophils, and this may be followed by haematogenous dissemination to any organ. Subsequent development of a T-lymphocyte response brings the infection under control, resulting in a latent state in most exposed individuals.

**Clinical features**

Disease severity depends on the quantity of spores inhaled and the immune status of the host. In most cases, infection is asymptomatic. Pulmonary symptoms are the most common presentation, with fever, non-productive cough and an influenza-like illness. Erythema nodosum, myalgia and joint pain frequently occur, and chest radiography may reveal a pneumonitis with hilar or mediastinal lymphadenopathy.

Patients with pre-existing lung disease, such as chronic obstructive pulmonary disease (COPD) or emphysema, may develop chronic pulmonary histoplasmosis (CPH). The predominant features of this condition, which may easily be mistaken for tuberculosis, are fever, cough, dyspnoea, weight loss and night sweats. Radiological findings include fibrosis, nodules, cavitation and hilar/mediastinal lymphadenopathy.

Disease caused by *H. capsulatum* var. *duboisii* presents more commonly with papulonodular and ulcerating lesions of the skin and underlying subcutaneous tissue and bone (sometimes referred to as ‘African histoplasmosis’). Multiple lesions of the ribs are common and the bones of the limbs may be affected. Lung involvement is relatively rare. Radiological examination may show rounded foci of bone destruction, sometimes associated
with abscess formation. Other disease patterns include a visceral form with liver and splenic invasion, and disseminated disease. Acute disseminated histoplasmosis is seen with immunocompromise, including HIV infection. Features include fever, pancycopenia, hepatosplenomegaly, lymphadenopathy and often a papular skin eruption. Chronic disseminated disease presents with fever, anorexia and weight loss. Cutaneous and mucosal lesions, lymphadenopathy, hepatosplenomegaly and meningoencephalitis may develop. *Emergomyces africanaus* (formerly *Emmonsiella* sp.) is a dimorphic fungus recently described in South Africa, which causes a disseminated histoplasmosis-like illness, mainly associated with HIV infection. Histopathologically, yeast forms appear similar to histoplasmosis and can be distinguished only by PCR.

**Investigations**

Histoplasmosis should be suspected in endemic areas with every undiagnosed infection in which there are pulmonary signs, enlarged lymph nodes, hepatosplenomegaly or characteristic cutaneous/bony lesions. Radiological examination in long-standing cases may show calcified lesions in the lungs, spleen or other organs. In the more acute phases of the disease, single or multiple soft pulmonary shadows with enlarged tracheobronchial nodes are seen on chest X-ray.

Laboratory diagnosis is by direct detection (histopathology or antigen detection), culture and serology; although antigen detection is the most effective method, it is not widely available. Serology utilises complement fixation testing or immunodiffusion; interpretation is complex and requires a specialist. *Histoplasma* antigen may be detectable in blood or urine. Culture is definitive but slow (up to 12 weeks). Histopathology may show characteristic intracellular yeasts. Diagnosis of subcutaneous or bony infection is mainly by histopathological examination and/or culture.

**Management**

Mild pulmonary disease does not require treatment. However, if prolonged, it may be treated with itraconazole. More severe pulmonary disease is treated with an amphotericin B formulation for 2 weeks, followed by itraconazole for 12 weeks, with methylprednisolone added for the first 2 weeks of therapy if there is hypoxia or ARDS. CPH is treated with itraconazole oral solution for 12–24 months, and disseminated histoplasmosis with an amphotericin B formulation followed by itraconazole. Lipid formulations of amphotericin B are preferred but their use is subject to availability. In subcutaneous and bone infection, patterns of remission and relapse are more common than cure. A solitary bony lesion may require local surgical treatment only.

**Coccidioidomycosis**

This is a primary systemic mycosis caused by the dimorphic fungi *Coccidioides immitis* and *C. posadasii*, found in the south-western USA and Central and South America. The disease is acquired by inhalation of conidia (arthrospores). In 60% of cases it is asymptomatic but in the remainder it affects the lungs, lymph nodes and skin. Rarely (in approximately 0.5%), it may spread haematogenously to bones, adrenal glands, meninges and other organs, particularly in those with immunocompromise.

Pulmonary coccidioidomycosis has two forms: primary and progressive. If symptomatic, primary coccidioidomycosis presents with cough, fever, chest pain, dyspnoea and (commonly) arthritis and a rash (erythema multiforme). Progressive disease presents with systemic upset (e.g. fever, weight loss, anorexia) and features of lobar pneumonia, and may resemble tuberculosis.

Coccidioides meningitis (which may be associated with CSF eosinophils) is the most severe disease manifestation; it is fatal if untreated and requires life-long suppressive therapy with antifungal azoles.

**Investigations and management**

Diagnosis is by direct histopathological detection in specimens, culture of infected tissue or fluids, or antibody detection. IgM may be detected after 1–3 weeks of disease by precipitin tests. IgG appears later and is detected with the complement fixation test. Change in IgG titre may be used to monitor clinical progress.

Treatment depends on specific disease manifestations and ranges from regular clinical reassessment without antifungal therapy (in mild pulmonary, asymptomatic cavitary or single nodular disease) to high-dose treatment with an antifungal azole, which may be continued indefinitely (e.g. in meningitis). Amphotericin B is used in diffuse pneumonia, disseminated disease and, intrathecal, in meningitis. Posaconazole has been used successfully in refractory disease.

**Paracoccidioidomycosis**

This is a primary systemic mycosis caused by inhalation of the dimorphic fungus *Paracoccidioides brasilensis*, which is restricted to South America. The disease affects the lungs, mucous membranes (painful destructive ulceration in 50% of cases), skin, lymph nodes and adrenal glands (hypoadrenalism). Diagnosis is by microscopy and culture of lesions, and antibody detection. Oral itraconazole solution (200 mg/day) has demonstrated 98% efficacy and is currently the treatment of choice (mean duration 6 months). Ketoconazole, fluconazole, voriconazole and 2–3-year courses of sulphonamides are alternatives. Amphotericin B is used in severe or refractory disease, followed by an azole or sulphonamide.

**Blastomycosis**

*Blastomyces dermatitidis* is a dimorphic fungus endemic to restricted parts of North America, mainly around the Mississippi and Ohio rivers. Very occasionally, it is reported from Africa. The disease usually presents as a chronic pneumonia similar to pulmonary tuberculosis. Bones, skin and the genitourinary tract may also be affected. Diagnosis is by culture of the organism or identification of the characteristic yeast form in a clinical specimen. Antibody detection is rarely helpful. Treatment is with amphotericin B (severe disease) or itraconazole.

Kaposi’s sarcoma  
Lymphoma (cerebral or B-cell non-Hodgkin)  
Mycobacterial infection, non-tuberculous, extrapulmonary or disseminated  
Mycosis – disseminated endemic (e.g. coccidioidomycosis, talaromycosis (formerly penicilliosis), histoplasmosis)  
Pneumocystis pneumonia  
Pneumonia, recurrent bacterial  
Progressive multifocal leucoencephalopathy  
Toxoplasmosis – cerebral  
Tuberculosis – extrapulmonary (CDC includes pulmonary)  
Sepsis, recurrent (including non-typhoidal Salmonella) (CDC only includes Salmonella)  
Symptomatic HIV-associated nephropathy*  
Symptomatic HIV-associated cardiomyopathy*  
Leishmaniasis, atypical disseminated* |
| **Stage 4**  
|  
Symptomatic HIV-associated nephropathy*  
Symptomatic HIV-associated cardiomyopathy*  
Leishmaniasis, atypical disseminated* |

*These conditions are in WHO stage 4 but not in CDC category C.
Epidemiology

The acquired immunodeficiency syndrome (AIDS) was first recognised in 1981, although the earliest documented case of HIV infection has been traced to a blood sample from the Democratic Republic of Congo in 1959. AIDS is caused by the human immunodeficiency virus (HIV), which progressively impairs cellular immunity. The origin of HIV is a zoonotic infection with simian immunodeficiency viruses (SIV) from African primates, probably first infecting local hunters. SIVs do not cause disease in their natural primate hosts. HIV-1 was transmitted from chimpanzees and HIV-2 from sooty mangabey monkeys. HIV-1 is the cause of the global HIV pandemic, while HIV-2, which causes a similar illness to HIV-1 but progresses more slowly and is less transmissible, is restricted mainly to western Africa. It has been estimated that both HIV-1 and HIV-2 first infected humans about 100 years ago. HIV-2 will not be discussed further in this chapter.

There are three groups of HIV-1, representing three separate transmission events from chimpanzees: M (‘major’, worldwide distribution), O (‘outlier’) and N (‘non-major and non-outlier’). Groups O and N are restricted to West Africa. Group M consists of nine subtypes: A–D, F–H, J and K (subtypes E and I were subsequently shown to be recombinants of other subtypes). Globally, subtype C (which predominates in sub-Saharan Africa and India) accounts for half of infections and appears to be more readily transmitted. Subtype B predominates in Western Europe, the Americas and Australia. In Europe, the prevalence of non-B subtypes is increasing because of migration. Subtypes A and D are associated with slower and faster disease progression, respectively.

Global and regional epidemics

In 2015 it was estimated that there were 36.7 million people living with HIV/AIDS, 2.1 million new infections and 1.1 million AIDS-related deaths. The global epidemiology of HIV has been changed by expanding access to combination antiretroviral therapy (ART), which reached 17 million people in 2015: the annual number of AIDS-related deaths has almost halved since the peak in 2005, the number of new infections has decreased by 40% since the peak in 1997, and the number of people living with HIV has increased. Regions have marked differences in HIV prevalence, incidence and dominant modes of transmission (Box 12.1). HIV has had a devastating impact in sub-Saharan Africa, particularly in southern Africa, where average life expectancy of the general population fell to below 40 years before the introduction of ART.

Modes of transmission

HIV is transmitted by sexual contact, by exposure to blood (e.g. injection drug use, occupational exposure in health-care workers) and blood products, or to infants of HIV-infected mothers (who may be infected in utero, perinatally or via breastfeeding). Worldwide, the major route of transmission is heterosexual. The risk of contracting HIV after exposure to infected body fluid is dependent on the integrity of the exposed site, the type and volume of fluid, and the level of viraemia in the source person. The approximate transmission risk after exposure is given in Box 12.2. Factors that increase the risk of transmission are listed in Box 12.3.

A high proportion of patients with haemophilia in high-income countries had been infected through contaminated blood products by the time HIV antibody screening was adopted in 1985. Routine screening of blood and blood products for HIV infection has virtually eliminated this as a mode of transmission. However, the World Health Organisation (WHO) estimates that, because of the lack of adequate screening facilities in resource-poor countries, 5–10% of blood transfusions globally are with HIV-infected blood.

(IDU = injection drug-users; MSM = men who have sex with men)
HIV is an enveloped ribonucleic acid (RNA) retrovirus from the lentivirus family. After mucosal exposure, HIV is transported via dendritic cells to the lymph nodes, where infection becomes established. This is followed by viraemia and dissemination to lymphoid organs, which are the main sites of viral replication.

Each mature virion has a lipid membrane lined by a matrix protein that is studded with glycoprotein (gp) 120 and gp41 spikes. The inner cone-shaped protein core (p24) houses two copies of the single-stranded RNA genome and viral enzymes. The HIV genome consists of three characteristic retroviral genes – gag (encodes a polyprotein that is processed into structural proteins, including p24), pol (codes for the enzymes reverse transcriptase, integrase and protease) and env (codes for envelope proteins gp120 and gp41) – as well as six regulatory genes.

HIV infects cells bearing the CD4 receptor; these are T-helper lymphocytes, monocyte–macrophages, dendritic cells, and microglial cells in the central nervous system (CNS). Entry into the cell commences with binding of gp120 to the CD4 receptor (Fig. 12.1), which results in a conformational change in gp120 that permits binding to one of two chemokine co-receptors (CXCR4 or CCR5). The chemokine co-receptor CCR5 is utilised during initial infection, but later on the virus may adapt to use CXCR4. Individuals who are homozygous for the CCR5 delta

Fig. 12.1 Life cycle of HIV. Red arrows indicate sites of action of antiretroviral drugs.
32 mutation do not express CCR5 on CD4 cells and are immune to HIV infection. Chemokine co-receptor binding is followed by membrane fusion and cellular entry involving gp41. After penetrating the cell and uncoating, a deoxyribonucleic acid (DNA) copy is transcribed from the RNA genome by the reverse transcriptase enzyme, which is carried by the infecting virion. Reverse transcription is an error-prone process and multiple mutations arise with ongoing replication, which results in considerable viral genetic heterogeneity. Viral DNA is transported into the nucleus and integrated within the host cell genome by the integrase enzyme. Integrated virus is known as proviral DNA and persists for the life of the cell. Cells infected with proviral HIV DNA produce new virions only if they undergo cellular activation, resulting in the transcription of viral messenger RNA (mRNA) copies, which are then translated into viral peptide chains. The precursor polypeptides are then cleaved by the viral protease enzyme to form new viral structural proteins and enzymes that migrate to the cell surface and are assembled using the host cellular apparatus to produce infectious viral particles; these bud from the cell surface, incorporating the host cell membrane into the viral envelope. The mature virion then infects other CD4 cells and the process is repeated. CD4 lymphocytes that are replicating HIV have a very short survival time of about 1 day. It has been estimated that in asymptomatic HIV-infected people, more than $10^{10}$ virions are produced and $10^9$ CD4 lymphocytes destroyed each day. The CD4 lymphocytes are destroyed primarily by the host immune response rather than by cytopathic effects of HIV.

A small percentage of T-helper lymphocytes enter a post-integration latent phase. Latently infected cells are important as sanctuary sites from antiretroviral drugs, which act only on replicating virus. Current ART is unable to eradicate HIV infection due to the persistence of proviral DNA in long-lived latent CD4 cells.

The host immune response to HIV infection is both humoral, with the development of antibodies to a wide range of antigens, and cellular, with a dramatic expansion of HIV-specific CD8 cytotoxic T lymphocytes, resulting in a CD8 lymphocytosis and reversal of the usual CD4:CD8 ratio. CD8 cytotoxic T lymphocytes kill activated CD4 cells that are replicating HIV, but not latently infected CD4 cells. HIV evades destruction despite this vigorous immune response, in part because the highly conserved regions of gp120 and gp41 that are necessary for viral attachment and entry are covered by highly variable glycoprotein loops that change over time as a result of mutations selected for by the immune response. The initial peak of viraemia in primary infection settles to a plateau phase of persistent chronic viraemia. With time, there is gradual attrition of the T-helper lymphocyte population and, as these cells are pivotal in orchestrating the immune response, the patient becomes susceptible to opportunistic infections. The predominant opportunistic infections in HIV-infected people are the consequences of impaired cell-mediated rather than antibody-mediated immunity (e.g. mycobacteria, herpesviruses). However, there is also a B-lymphocyte defect with impaired antibody production to new antigens and dysregulated antibody production with a polyclonal increase in gamma globulins, resulting in an increased risk of infection with encapsulated bacteria, notably Streptococcus pneumoniae.

The immune activation in response to HIV infection does not completely resolve on effective ART. This residual inflammatory state has been implicated in the pathogenesis of several non-AIDS morbidities that occur at a higher rate in HIV-infected people on ART than in the general population: cardiovascular, neurological and liver disease, chronic kidney disease and non-AIDS cancers.
antibodies have developed. PCR is more sensitive than p24 antigen detection for diagnosing primary infection.

The purpose of HIV testing is not simply to identify infected individuals, but also to educate people about prevention and transmission of the virus. Counselling in the client’s home language is essential both before testing and after the result is obtained (Boxes 12.5 and 12.6). There are major advantages to using rapid point-of-care HIV tests in that pre- and post-test counselling can be done at the same visit.

A number of baseline investigations should be done at the initial medical evaluation (Box 12.7). The extent of these investigations will depend on the resources available.

**Viral load and CD4 counts**

**CD4 counts**

CD4 lymphocyte counts are usually determined by flow cytometry but cheaper methods have been developed for low-income countries. The CD4 count is the most clinically useful laboratory indicator of the degree of immune suppression; it is used, together with clinical staging, in decisions to start prophylaxis against opportunistic infections, and is of great value in the differential diagnosis of clinical problems.

The CD4 count varies by up to 20% from day to day and is also transiently reduced by intercurrent infections. Due to this variability, major therapeutic decisions should not be taken on the basis of a single count. The percentage of lymphocytes that are CD4⁺, rather than the absolute count, is routinely used in paediatrics, as the normal CD4 counts in infants and young children are much higher than in adults. In adults, the CD4 percentage is occasionally useful when evaluating significant reductions in an individual’s CD4 count, which may be associated with transient lymphopenia due to intercurrent infection or pregnancy. In this case, the CD4 percentage will be unchanged.

The normal CD4 count is over 500 cells/mm³. The rate of decline in CD4 count is highly variable. People with CD4 counts between 200 and 500 cells/mm³ have a low risk of developing major opportunistic infections. Morbidity due to inflammatory dermatoses, herpes zoster, oral candidiasis, tuberculosis, bacterial pneumonia and HIV-related immune disorders (e.g. immune thrombocytopenia) becomes increasingly common as CD4 counts decline. Once the count is below 200 cells/mm³, there is severe immune suppression and a high risk of AIDS-defining conditions. It is important to note that patients can be asymptomatic despite very low CD4 counts and that major opportunistic diseases occasionally present with high CD4 counts.

The CD4 count should be performed every 3–6 months in patients on ART, together with measurement of the viral load.

**Viral load**

The level of viraemia is measured by quantitative PCR of HIV RNA, known as the viral load. Determining the viral load is crucial for monitoring responses to ART (p. 324). People with high viral loads (e.g. >100,000 copies/mL) experience more rapid declines in CD4 count, while those with low viral loads (<1000 copies/mL) usually have slow or even no decline in CD4 counts.

Transient increases in viral load occur with intercurrent infections and immunisations, so the test should be done at least 2 weeks afterwards. Viral loads are variable; only changes in viral load of more than 0.5 log₁₀ copies/mL are considered clinically significant.

**Clinical manifestations of HIV**

Clinical staging of patients should be done at the initial medical examination, as it provides prognostic information and is a key criterion for initiating prophylaxis against opportunistic infections. Two clinical staging systems are used internationally (p. 307). In both, patients are staged according to the most severe manifestation and do not improve their classification. For example, a patient who is asymptomatic following a major opportunistic disease (AIDS) remains at stage 4 or category C of the WHO and CDC systems, respectively, and never reverts to earlier stages. Finally, patients do not always progress steadily through all stages and may present with AIDS, having been asymptomatic.

**Primary HIV infection**

Primary infection is symptomatic in more than 50% of cases but the diagnosis is often missed. The incubation period is usually 2–4 weeks after exposure. The duration of symptoms is variable but is seldom longer than 2 weeks. The clinical manifestations (Box 12.9) resemble those of infectious mononucleosis/glandular fever (p. 241), but the presence of maculopapular rash or mucosal ulceration strongly suggests primary HIV infection.
response. The median time from infection to the development of AIDS in adults is about 9 years (see Fig. 12.2). A small proportion of untreated HIV-infected people are long-term non-progressors, with CD4 counts in the reference range for 10 years or more. Some long-term non-progressors have undetectable viral loads and are known as ‘elite controllers’.

**Minor HIV-associated disorders**

A wide range of disorders indicating some impairment of cellular immunity occur in most patients before they develop AIDS (CDC category B or WHO stages 2 and 3). Careful examination of the mouth is important when patients are being followed up, as oral candidiasis and oral hairy leucoplakia are common conditions that require initiation of prophylaxis against opportunistic infections, irrespective of the CD4 count.

**Acquired immunodeficiency syndrome**

AIDS is defined by the development of specified opportunistic infections, cancers and severe manifestations of HIV itself (p. 307). CDC category C is the most widely used definition of AIDS. WHO updated its classification more recently and added a few conditions of similar prognosis to its stage 4 disease.

**Presenting problems in HIV infection**

HIV itself is associated with a wide variety of clinical manifestations, and opportunistic diseases add many more. All body systems can be affected by HIV. The CD4 count is useful in differential diagnosis (Box 12.9): opportunistic diseases that may present at higher CD4 counts become increasingly common as CD4 counts decline, so the CD4 count helps to rule out certain disorders. For example, in a patient with a pulmonary infiltrate and a CD4 count of 350 cells/mm³, pulmonary tuberculosis is a likely diagnosis and PJP is very unlikely, but if the patient’s CD4 count is 50 cells/mm³, both PJP and tuberculosis are likely.

Globally, tuberculosis is the most common cause of morbidity and mortality in HIV-infected patients. Tuberculosis should be considered in the differential diagnosis of most presenting problems in patients from communities where tuberculosis is common.
Presenting problems in HIV infection

• 313

Lymph node needle aspiration (using a wide-bore needle such as 19G if tuberculosis is suspected) should be performed. One slide should be air-dried and sent for staining for acid-fast bacilli, which has about a 70% yield in tuberculosis. The other slide should be fixed and sent for cytology. If caseous liquid is aspirated, this should be sent for mycobacterial culture or PCR. If needle aspiration is unhelpful, or if lymphoma or Kaposi’s sarcoma is suspected, excision biopsy should be performed.

Weight loss

Weight loss is a very common finding in advanced HIV infection. The HIV wasting syndrome is an AIDS-defining condition and is defined as weight loss of more than 10% of body weight, plus either unexplained chronic diarrhoea (lasting over 1 month) or chronic weakness and unexplained prolonged fever (lasting over 1 month). This is a diagnosis of exclusion. If the weight loss is rapid (more than 1 kg a month), then major opportunistic infections or cancers become more likely. Painful oral conditions and nausea from drugs contribute by limiting intake. Depression is very common and can cause significant weight loss. Measurement of C-reactive protein is helpful in the work-up of weight loss, as this is markedly raised with most opportunistic diseases but not with HIV itself. Erythrocyte sedimentation rate (ESR) is elevated by HIV infection and is therefore not useful. The presence of fever or diarrhoea is helpful in the differential diagnosis of weight loss (Fig. 12.3).

Fever

Fever is a very common presenting feature. Common causes of prolonged fever with weight loss are listed in Figure 12.3. Non-typhoid Salmonella bacteraemia, which commonly presents with fever in low-income countries, is accompanied by diarrhoea in only about 50% of patients. Pyrexia of unknown origin (PUO) in HIV infection is defined as temperature over 38°C with no cause found after 4 weeks in outpatients or 3 days in inpatients, and initial investigations such as chest X-rays, urinalysis and

Lymphadenopathy

Persistent generalised lymphadenopathy due to HIV is described above under asymptomatic infection. Lymphadenopathy may also be due to malignancy (Kaposi’s sarcoma or lymphoma) or infections, especially tuberculosis, which is an extremely common cause in low- and middle-income countries. Tuberculous lymph nodes are often matted and may become fluctuant due to extensive caseous necrosis; inexperienced clinicians often perform incision and drainage inappropriately when simple aspiration is all that is required. Symmetrical generalised lymphadenopathy may occur in disseminated tuberculosis. Lymphoma typically presents with large, firm, asymmetric nodes. Rapid enlargement of a node, asymmetric enlargement or lymphadenopathy associated with constitutional symptoms (even if the nodes are symmetrical) warrants further investigation. Lymph node needle aspiration (using a wide-bore needle such as 19G if tuberculosis is suspected) should be performed. One slide should be air-dried and sent for staining for acid-fast bacilli, which has about a 70% yield in tuberculosis. The other slide should be fixed and sent for cytology. Fever

Fever is a very common presenting feature. Common causes of prolonged fever with weight loss are listed in Figure 12.3. Non-typhoid Salmonella bacteraemia, which commonly presents with fever in low-income countries, is accompanied by diarrhoea in only about 50% of patients. Pyrexia of unknown origin (PUO) in HIV infection is defined as temperature over 38°C with no cause found after 4 weeks in outpatients or 3 days in inpatients, and initial investigations such as chest X-rays, urinalysis and
blood cultures have failed to identify the cause. HIV itself can present with prolonged fever but this is a diagnosis of exclusion, as a treatable cause will be found in most patients. Abdominal imaging, preferably by computed tomography (CT), should be requested. Abdominal nodes (especially if they are hypodense in the centre) or splenic microabscesses strongly suggest tuberculosis. Mycobacterial blood cultures, which can also detect fungi, should be performed. Bone marrow aspirate and trephine biopsy are helpful if the full blood count shows cytopenias. Liver biopsy may be helpful if the liver enzymes are elevated but is invasive and seldom necessary. Mycobacterial and fungal stains and cultures should be done on all biopsies. Chest X-rays should be repeated after about a week, as micronodular or interstitial infiltrates may have become apparent (see p. 319 for differential diagnosis).

Tuberculosis is by far the most common cause of PUO in low- and middle-income countries, and in these settings a trial of empirical therapy is warranted after cultures have been sent. In high-income countries, disseminated Mycobacterium avium complex (MAC) infection is an important cause of PUO, often also presenting with diarrhoea and splenomegaly. Disseminated endemic mycoses (e.g. histoplasmosis, coccidioidomycosis, talaromycosis) present with PUO, often with papular skin eruptions or mucosal ulcerations (Fig. 12.4). Skin biopsy for histology and fungal culture is often diagnostic.

**Mucocutaneous disease**

The skin and mouth must be carefully examined, as mucocutaneous manifestations are extremely common in HIV and many prognostically important conditions can be diagnosed by simple inspection. The differential diagnosis of dermatological conditions is simplified by categorising disorders according to the lesion type (Box 12.10). Some common dermatological diseases, notably psoriasis, are exacerbated by HIV. The risk of many drug rashes is increased in HIV-infected patients. Skin biopsy should be taken, and sent for histology and culture for mycobacteria and fungi, in patients with papular rashes or if there are constitutional symptoms coinciding with the development of the rash.

**Seborrhoeic dermatitis**

Seborrhoeic dermatitis is very common in HIV. The severity increases as the CD4 count falls. It presents as scaly red patches, typically in the nasolabial folds and in hairy areas. Fungal infections are thought to play a role in the pathogenesis of this condition. It responds well to a combined topical antifungal and glucocorticoid. Selenium sulphide shampoo is helpful for scalp involvement.

*See Chapter 29 for more information.
Post-herpetic neuralgia is difficult to manage. Analgesic adjuvants, of aciclovir or its congeners should be given for all cases with a higher risk of developing post-herpetic neuralgia. High doses of dissemination is rare. In HIV-infected patients, zoster is may be multidermatomal and recurrent episodes may occur.

Topical capsaicin has modest effect. e.g. amitriptyline and pregabalin, should be commenced in all patients with prolonged pain.

KS occurs in four patterns:

- **classic KS**: rare, indolent and restricted largely to elderly Mediterranean or Jewish men
- **endemic KS**: occurs in sub-Saharan Africa, is more aggressive, presents at earlier ages than classic KS, and affects men more than women
- **KS in patients on immunosuppressant drugs**: usually transplant recipients, who experience disseminated disease
- **AIDS-associated KS**.

In Africa, the male-to-female ratio of AIDS-associated KS is much lower than is seen with endemic KS, but men are still more affected than women, despite the fact that the seroprevalence of human herpesvirus 8 is the same in both sexes.

AIDS-associated KS is always a multicentric disease. Early mucocutaneous lesions are macular and may be difficult to diagnose. Subsequently, lesions become more extensive and may ulcerate. KS lesions typically have a red–purple colour (Fig. 12.6 and p. 306) but may become hyperpigmented, especially in dark-skinned patients. As the disease progresses, the skin lesions become more numerous and larger. Lymphoedema is common, as lymphatic vessels are infiltrated. KS also commonly spreads to lymph nodes and icularly, especially to the lungs and gastrointestinal tract. Visceral disease occasionally occurs in the absence of mucocutaneous involvement. B symptoms of fever, night sweats and weight loss may occur.

KS may respond to ART. Chemotherapy should be reserved for patients who fail to remit on ART, or be given together with ART if there are poor prognostic features such as visceral involvement, oedema, ulcerated lesions and B symptoms.

Bacillary angiomatosis

Bacillary angiomatosis is a bacterial infection caused by *Bartonella henselae* or *B. quintana*. Skin lesions range from solitary superficial red–purple lesions resembling KS or pyogenic granuloma, to

*Secondary prophylaxis may be discontinued once CD4 counts have increased to >200 cells/mm³ on antiretroviral therapy for at least 3 months.*
multiple subcutaneous nodules or plaques. Lesions are painful and may bleed or ulcerate. The infection may become disseminated with fevers, lymphadenopathy and hepatosplenomegaly. Diagnosis is made by biopsy of a lesion and Warthin–Starry silver staining, which reveals aggregates of bacilli. Treatment with doxycycline or azithromycin is effective.

**Papular pruritic eruption**

Papular pruritic eruption (‘itchy red bump disease’) is an intensely itchy, symmetrical rash affecting the trunk and extremities. It is thought to be due to an allergic reaction to insect bites. In sub-Saharan Africa, it is the most common skin manifestation of HIV. Post-inflammatory hyperpigmentation is common. Topical glucocorticoids, emollients and antihistamines are useful but response is variable. Measures to reduce insect bites are logical but difficult to implement in low-income settings.

**Drug rashes**

Cutaneous hypersensitivity to drugs is said to occur 100 times more frequently in HIV infection. The most common type is an erythematous maculopapular rash, which may be scaly. The drugs most commonly associated with rashes are sulphonamides and non-nucleoside reverse transcriptase inhibitors (NNRTIs – see below). Severe, life-threatening features of drug rashes include blistering (when this affects more than 30% of surface area it is known as toxic epidermal necrolysis), involvement of mucous membranes (Stevens–Johnson syndrome, pp. 1224 and 1254), or systemic involvement with fever or organ dysfunction (especially hepatitis, which is often delayed for a week or two after the rash develops). Because sulphonamides are important in the treatment and prophylaxis of opportunistic infections, rechallenge or desensitisation is often attempted in patients who have previously experienced rashes, provided the reaction was not life-threatening. Details of rashes caused by ART are given below.

**Oral conditions**

Oropharyngeal candidiasis is very common. It is nearly always caused by *C. albicans* (p. 300), but azole-resistant *Candida* species may be selected for if there have been repeated courses of azole drugs. Pseudomembranous candidiasis is the most common manifestation, with white patches on the buccal mucosa (p. 306) that can be scraped off to reveal a red raw surface. Erythematous candidiasis is more difficult to diagnose and presents with a reddened mucosa and a smooth shiny tongue. Angular cheilitis due to *Candida* is a common manifestation. Topical antifungals are usually effective. Antifungal lozenges are more effective than antifungal solutions. Systemic azole therapy, usually fluconazole, should be given if topical therapy fails or if there are oesophageal symptoms.

Oral hairy leucoplakia (p. 306) appears as corrugated white plaques running vertically on the side of the tongue and is virtually pathognomonic of HIV disease. It is usually asymptomatic and is due to EBV.

Oral ulcers are common. Herpetiform oral ulcers occur in primary infection. Herpes simplex typically affects the nasolabial area but may cause oral ulcers. In early disease, minor aphthous ulcers are common. In advanced disease, giant aphthous ulcers occur. These destroy tissue, are painful and need to be differentiated from herpes simplex and CMV ulcers by biopsy. They respond to systemic glucocorticoids and ART. A number of disseminated endemic mycoses, notably histoplasmosis (p. 303), may cause oral ulcers, usually associated with constitutional symptoms. Finally, superficial oral ulcers may occur as part of the Stevens–Johnson syndrome, usually caused by sulphonamides or NNRTIs.

KS often involves the mouth, especially the hard palate (see above and Fig. 12.6). Nodular oral lesions are associated with a worse prognosis.

Gingivitis is very common. Good oral hygiene and regular dental check-ups are important. Acute necrotising ulcerative gingivitis and periodontitis (p. 306) can result in loss of teeth; they should be treated with a course of metronidazole and a dental referral should be made.

**Nail disorders**

Fungal infections (onychomycosis, p. 1240) are very common and often involve multiple nails. Blue–black discolouration of nails is common and may be due to HIV or to the antiretroviral drug zidovudine.

## Gastrointestinal disease

**Oesophageal diseases**

Oesophageal candidiasis (Fig. 12.7) is the most common cause of pain on swallowing (odynophagia), dysphagia and regurgitation. Concomitant oral candidiasis is present in about 70% of patients. Systemic azole therapy, e.g. fluconazole 200 mg daily for 14 days, is usually curative but relapses are common (Box 12.11). Patients whose oesophageal symptoms fail to respond to azoles should be investigated with oesophagoscopy. Major aphthous ulceration and CMV ulcers are the most likely causes and need to be differentiated by biopsy. Occasionally, herpes simplex oesophagitis or KS is responsible.

**Diarrhoea**

Chronic diarrhoea is a very common presenting problem in patients with advanced HIV, especially in areas where there is no access to safe water. It is a major cause of wasting. The differential diagnosis of diarrhoea depends on whether the presentation is with large- or small-bowel symptoms (see Fig. 12.3). The presentation and aetiology of acute diarrhoea are similar to those in HIV-uninfected patients.
Presenting problems in HIV infection

fever, weight loss and diarrhoea, but the diarrhoea is seldom profuse.

Hepatobiliary disease

Fig. 12.7 Oesophageal candidiasis. Endoscopy showing typical pseudomembranous candidiasis.

Large-bowel diarrhoea

Acute diarrhoea caused by the bacterial enteric pathogens Campylobacter, Shigella and Salmonella occurs more frequently than in HIV-uninfected people and the illness is more severe. Bacteraemia is much more common, notably due to non-typhoid Salmonella (p. 262). Diarrhoea caused by Clostridium difficile should be considered if there has been prior exposure to antibiotics, as is often the case in patients with symptomatic HIV.

CMV colitis presents with chronic large-bowel symptoms and fever in patients with CD4 counts below 100 cells/mm³. On colonoscopy, ulcers are seen, mostly involving the left side of the colon. Biopsy of ulcers shows typical ‘owl’s-eye’ inclusion bodies.

Small-bowel diarrhoea

Chronic small-bowel diarrhoea may be due to HIV enteropathy but this is a diagnosis of exclusion. It typically presents with chronic watery diarrhoea and wasting without fever. Infection with one of three unicellular organisms is responsible for most cases: cryptosporidiosis, microsporidiosis and cystoisosporiasis (formerly known as isosporiasis) (Box 12.12). All three organisms are intracellular parasites that invade enterocytes. If the diagnosis is not made by stool microscopy on at least two specimens, a duodenal biopsy should be performed (Fig. 12.8). Electron microscopy is essential for speciation of microsporidia.

About 40% of patients with disseminated MAC infections have watery diarrhoea. Fever is a prominent feature of MAC infection, which helps differentiate it from cryptosporidiosis, microsporidiosis and cystoisosporiasis. Intestinal tuberculosis typically involves the ileocaecal area and may present with fever, weight loss and diarrhoea, but the diarrhoea is seldom profuse.

Hepatitis B

Hepatitis B and/or C (HBV and HCV) co-infection is common in HIV-infected people due to shared risk factors for transmission. The natural history of both HBV and HCV is altered by HIV co-infection. In the ART era, chronic liver disease from viral hepatitis has emerged as a major cause of morbidity and mortality. HBV and HCV are further described on pages 873 and 877.

Hepatitis C

HIV infection is common in several groups of people at risk of HIV infection: residents of low- and middle-income countries, injection drug-users, haemophiliacs and MSM. HIV co-infection increases HBV viraemia, is associated with less elevation of transaminase (presumably due to immune suppression), and increases the risk of liver fibrosis and hepatocellular carcinoma. Several nucleoside reverse transcriptase inhibitors (NRTIs; lamivudine, emtricitabine and tenofovir) are also effective against HBV. HBV status should be checked at baseline in all HIV-infected patients. Treatment with anti-HBV drugs should be considered for all patients who have active HBV replication (HBcAg-positive or HBV DNA >2000 IU/mL) and/or evidence of inflammation or fibrosis on liver biopsy (see also p. 876). A flare of hepatitis may be associated with improved immune function after starting ART or discontinuing

</table>
antiretrovirals that have anti-HBV activity. HBV co-infection increases the risk of antiretroviral hepatotoxicity.

**Hepatitis C**

HCV infection is extremely common in injection drug-users and haemophiliacs. HCV co-infection increases HCV viraemia and increases the risk of liver fibrosis and hepatocellular carcinoma. Treatment for HCV should preferably be deferred in patients with CD4 counts <200 cells/mm³ until they are stable on ART. As with HBV co-infection, a flare of hepatitis may be associated with improved immune function after starting ART, and there is an increased risk of antiretroviral hepatotoxicity. Response to anti-HCV therapy is similar to that seen in HIV-uninfected people, but there are important drug–drug interactions between several antiretrovirals and the newer HCV protease inhibitors.

**HIV cholangiopathy**

HIV cholangiopathy, a form of secondary sclerosing cholangitis (p. 888), may occur in patients with severe immune suppression. In some patients, coexisting intestinal infection with CMV, cryptosporidiosis or microsporidiosis is present, but it is uncertain if these organisms play an aetiological role. Papillary stenosis is common and is amenable to cautery via endoscopic retrograde cholangiopancreatography (ERCP), which provides symptomatic relief. Acalculous cholecystitis is a common complication of cholangiopathy. ART may improve the condition.

**Respiratory disease**

Pulmonary disease is very common and is the major reason for hospital admission. Most patients who are admitted for respiratory diseases will have either bacterial pneumonia, pulmonary tuberculosis or PJP. PJP is more common in high-income countries, whereas tuberculosis is more common in low- and middle-income countries. An approach to the differential diagnosis of all three conditions is given in Box 12.13.

**Pneumocystis jirovecii pneumonia**

The key presenting feature of Pneumocystis jirovecii pneumonia (PJP) is progressive dyspnoea with a duration of less than 12 weeks. Dry cough and fever are common. The chest X-ray typically shows a bilateral interstitial infiltrate spreading out from the hilar regions (Fig. 12.9) but may be normal initially. High-resolution CT scan is more sensitive than chest X-ray, usually showing typical ‘ground-glass’ interstitial infiltrates. Pneumatoceles may occur and may rupture, resulting in a pneumothorax. The diagnosis is made with silver stains, PCR or immunofluorescence of broncho-alveolar lavage or induced sputum (note that spontaneously produced sputum should not be sent, as the yield is low). Treatment is with high-dose co-trimoxazole, together with adjunctive systemic glucocorticoids if the patient is hypoxic (see Box 12.11).

**Pulmonary tuberculosis**

Tuberculosis is the most common cause of admission in countries with a high tuberculosis incidence. Pulmonary tuberculosis in patients with mild immune suppression typically presents as in HIV-uninfected patients, with a chronic illness and apical pulmonary cavities (p. 588). However, in patients with CD4 counts below 200 cells/mm³, there are four important differences in the clinical presentation of pulmonary tuberculosis:

- Tuberculosis progresses more rapidly, with a subacute or even acute presentation. The diagnosis therefore needs to be made and therapy commenced promptly. A trial of empirical therapy is often started while awaiting the results of mycobacterial cultures.
- The chest X-ray appearance alters: cavities are rarely seen, pulmonary infiltrates are no longer predominantly in apical areas, and pleural effusions and hilar or mediastinal lymphadenopathy are common (Fig. 12.10). A normal chest X-ray is not unusual in symptomatic patients with tuberculosis confirmed on sputum culture. These atypical findings can result in a delayed or missed diagnosis.
- Sputum smears, which are positive in most HIV-uninfected adults with pulmonary tuberculosis, are negative in more than half of patients. The main reason for this is the absence of pulmonary cavities.
- Many patients have disseminated tuberculosis, sometimes with a classic miliary pattern on chest X-ray, but more
Presenting problems in HIV infection

Lymphoid interstitial pneumonitis is a slowly progressive disorder causing a diffuse reticulonodular infiltrate. It is caused by a benign polyclonal lymphocytic interstitial infiltrate and is part of the diffuse infiltrative lymphocytosis syndrome (DILS – see p. 321). Patients may have other features of DILS, notably parotidomegaly. KS often spreads to the lungs. Typical chest X-ray appearances are large, irregular nodules, linear reticuloid patterns and pleural effusions. Bronchoscopy is diagnostic.

Nervous system and eye disease

The central and peripheral nervous systems are commonly involved in HIV, either as a direct consequence of HIV infection or due to opportunistic diseases. An approach to common presentations is outlined in Figure 12.11.

Cognitive impairment

HIV-associated neurocognitive disorders

HIV is a neurotropic virus and invades the CNS early during infection. Meningo-encephalitis may occur at seroconversion. About 50% of HIV-infected people have abnormal neuropsychiatric testing. The term HIV-associated neurocognitive disorder (HAND) describes a spectrum of disorders: asymptomatic neurocognitive impairment (which is the most common), minor neurocognitive disorder and HIV-associated dementia (also called HIV encephalopathy). The proportion of patients with symptomatic HAND increases with declining CD4 counts. HIV-associated dementia is a subcortical dementia characterised by impairment of executive function, psychomotor retardation and impaired memory. There is no diagnostic test for HIV-associated dementia. CT or magnetic resonance imaging (MRI) shows diffuse cerebral atrophy out of keeping with age. It is important to exclude depression, cryptococcal meningitis and neurosyphilis. ART usually improves HIV-associated dementia but milder forms of HAND often persist.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a progressive disease that presents with stroke-like episodes and cognitive

Miscellaneous causes of pulmonary infiltrates

Pulmonary cryptococcosis may present as a component of disseminated disease or be limited to the lungs. The chest X-ray appearances are variable. Cryptococcomas occur less commonly than in HIV-uninfected people. The most common radiographic pattern seen in HIV infection is patchy consolidation, often with small areas of cavitation resembling tuberculosis. Pleural involvement is rare. The disseminated endemic mycoses (histoplasmosis, coccidioidomycosis and talaromycosis) often cause diffuse pulmonary infiltrates, mimicking miliary tuberculosis.

Bacterial pneumonia

The incidence of bacterial pneumonia is increased about 100-fold by HIV infection. The severity, likelihood of bacteraemia, risk of recurrent pneumonia, and mortality are all increased compared with HIV-uninfected patients. The aetiology is similar to that of community-acquired pneumonia in HIV-uninfected patients with co-morbidity: S. pneumoniae is the most common cause, followed by Haemophilus influenzae, Enterobacteriaceae (e.g. Klebsiella pneumoniae) and Staphylococcus aureus. The prevalence of atypical bacteria in HIV-infected patients with pneumonia is similar to that in the general population. Treatment is with a broad-spectrum β-lactam (e.g. ceftriaxone, amoxicillin–clavulanate), with the addition of a macrolide if the pneumonia is severe. Uncommon bacteria causing pneumonia include Pseudomonas aeruginosa, Nocardia (which mimics tuberculosis) and Rhodococcus equi (which can cause pulmonary cavities).

Fig. 12.10 Chest X-ray of pulmonary tuberculosis in advanced HIV infection. Lower-zone infiltrates and hilar or mediastinal nodes in a patient with a CD4 count of <200 cells/mm³.
Primary CNS lymphoma (PCNSLs) are high-grade B-cell lymphomas associated with EBV infection. Characteristically, imaging demonstrates a single homogeneously enhancing, periventricular lesion with surrounding oedema (Fig. 12.14). If it is considered safe to perform a lumbar puncture, PCR for EBV DNA in the cerebrospinal fluid (CSF) by PCR is diagnostic. No specific treatment exists and prognosis remains poor despite ART.

**Tuberculoma**
Lesions resemble toxoplasmic lesions on imaging, except that oedema tends to be less marked and single lesions occur more commonly.
There may be evidence of tuberculosis elsewhere. The CSF may show features consistent with tuberculous meningitis. Response to antituberculosis therapy is slow and paradoxical expansion of lesions despite therapy is not uncommon.

**Stroke**

There is a higher incidence of stroke in patients with HIV disease. Atherosclerosis is accelerated by the presence of inflammation due to the immune response to HIV, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs. HIV vasculopathy, which is thought to be a vasculitis, can also cause a stroke. It is important to exclude tuberculous meningitis and meningovascular syphilis in all patients who present with a stroke.

**Meningitis**

**Cryptococcal meningitis**

_Cryptococcus neoformans_ is the most common cause of meningitis in AIDS patients. Patients usually present subacutely with headache, vomiting and decreased level of consciousness. Neck stiffness is present in less than half. CSF pleocytosis is often mild or even absent, and protein and glucose concentrations are variable. It is important to request CSF cryptococcal antigen tests in all HIV-infected patients undergoing lumbar puncture, as this test has a high sensitivity and specificity. Treatment is with amphotericin B (plus flucytosine if available) for 2 weeks, followed by fluconazole (see Box 12.11). Raised intracranial pressure is common and should be treated with repeated therapeutic lumbar punctures, removing sufficient CSF to reduce pressure to less than 20 cmH₂O. (Most experts are reluctant to withdraw more than 30 mL at a time.)

**Tuberculous meningitis**

The presentation and CSF findings of tuberculous meningitis are similar to those in HIV-uninfected patients (p. 1120), except that concomitant tuberculosis at other sites is more common in HIV infection.

**Peripheral nerve disease**

HIV infection causes axonal degeneration, resulting in a sensorimotor peripheral neuropathy in about one-third of AIDS patients. The incidence increases with lower CD4 counts, older age and increased height. Sensory symptoms predominate. Treatment involves foot care, analgesia and analgesic adjuvants. ART has minimal effect on halting or reversing the process. The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in HIV-infected people.

**Myelopathy and radiculopathy**

The most common cause of myelopathy in HIV infection is cord compression from tuberculous spondylitis. Vascular myelopathy is seen in advanced disease and is due to HIV. It typically presents with a slowly progressive paraparesis with no sensory level. MRI of the spine is normal but is an important investigation to exclude other causes. Most patients have concomitant HIV-associated dementia.

CMV polyradiculitis presents with painful legs, progressive flaccid paraparesis, saddle anaesthesia, absent reflexes and sphincter dysfunction. CSF shows a neutrophil pleocytosis (which is unusual for a viral infection), and the detection of CMV DNA by PCR confirms the diagnosis. Functional recovery is poor despite treatment with ganciclovir or valganciclovir.

**Psychiatric disease**

Significant psychiatric morbidity is very common and is a major risk factor for poor adherence. Reactive depression is the most common disorder. Diagnosis is often difficult, as many patients have concomitant HAND. Substance misuse is common in many groups of people at risk of HIV. Some antiretroviral drugs can cause psychiatric adverse effects and these are detailed on page 326.

**Retinopathy**

CMV retinitis presents with painless, progressive visual loss in patients with severe immune suppression. On fundoscopy, the vitreous is clear. Haemorrhages and exudates are seen in the retina (p. 306), often with sheathing of vessels (‘frosted branch angitis’). The disease usually starts unilaterally but progressive bilateral involvement occurs in most untreated patients. Diagnosis is usually clinical, but if there is doubt, demonstrating CMV DNA by PCR of vitreous fluid is diagnostic. Treatment with ganciclovir or valganciclovir stops progression of the disease but lost vision does not recover. Some patients may develop immune recovery uveitis in response to ART, with intraocular inflammation, macular oedema and cataract formation that require prompt treatment with oral and intraocular glucocorticoids to prevent further visual loss. Three other conditions may mimic CMV retinitis: ocular toxoplasmosis, which typically presents with a vitritis and retinitis without retinal haemorrhages; HIV retinopathy, a microangiopathy that causes cotton wool spots, which are not sight-threatening; and varicella zoster virus, which can cause rapidly progressive outer retinal necrosis.

**Rheumatological disease**

The immune dysregulation associated with HIV infection may result in autoantibody formation, usually in low titres. Mild arthralgias and a fibromyalgia-like syndrome are common in HIV-infected people.

**Arthritis**

HIV can cause a seronegative arthritis, which resembles rheumatoid arthritis. A more benign oligoarthritis may also occur. Reactive arthritis is more severe in HIV infection (p. 1031).

**Diffuse infiltrative lymphocytosis syndrome**

Diffuse infiltrative lymphocytosis syndrome (DILS) is a benign disorder involving polyclonal CD8 lymphocytic infiltration of tissues, which has some features in common with Sjögren’s syndrome (p. 1038). It is linked to human leucocyte antigen (HLA)-DRB1. Most patients have a marked CD8 lymphocytosis. DILS usually presents in patients with mild immune suppression. The most common manifestation is bilateral parotid gland enlargement; the glands are often massive, with lymphoepithelial cysts
is immune-mediated platelet destruction resembling idiopathic thrombocytopenic purpura (p. 971). This responds to glucocorticoids or intravenous immunoglobulin, together with ART. Splenectomy should be avoided if possible because it further increases the risk of infection with encapsulated bacteria. Severe thrombocytopenia with a microangiopathic anaemia also occurs in a thrombotic thrombocytopenic purpura-like illness (p. 979), which has a better prognosis and fewer relapses than the classical disease.

Renal disease

Acute kidney injury is common, usually due to acute infection or nephrotoxicity of drugs (e.g. tenofovir (p. 412), amphotericin B (p. 126)). HIV-associated nephropathy (HIVAN) is the most important cause of chronic kidney disease (CKD) and is seen most frequently in patients of African descent and those with low CD4 counts. Progression to end-stage disease is more rapid than with most other causes of CKD, and renal size is usually preserved. HIVAN presents with nephrotic syndrome, CKD or a combination of both. ART has some effect in slowing progression of HIVAN. Other important HIV-associated renal diseases include HIV immune complex kidney diseases and thrombotic microangiopathy. With the overall improvement in life expectancy from ART, conditions such as diabetes mellitus, hypertension and vascular disease add to the burden of CKD. Outcomes of renal transplantation are good in patients on ART.

Cardiac disease

HIV-associated cardiomyopathy resembles idiopathic dilated cardiomyopathy (p. 539) but progresses more rapidly. ART may improve cardiac failure but does not reverse established cardiomyopathy. Pericardial disease due to opportunistic diseases is not uncommon. Globally, the most common cause is tuberculous pericardial effusions. Tuberculous constrictive pericarditis is less common than in HIV-uninfected people. KS and lymphoma may cause pericardial effusions. Septic pericarditis, usually due to S. pneumoniae, is uncommon.

HIV is associated with an increased risk of myocardial infarction due to accelerated atherogenesis caused by the inflammatory state, which is not completely suppressed by ART, and by dyslipidaemia caused by some antiretroviral drugs.

HIV-related cancers

The AIDS-defining cancers are KS (see above), cervical cancer and non-Hodgkin lymphoma (NHL, p. 964). NHL may occur at any CD4 count but is more commonly seen with counts below 200 cells/mm³. Almost all NHLs are B-cell tumours and most are stage 3 or 4. Long-term remission rates similar to those in patients without HIV can be achieved with NHL in AIDS patients using ART and chemotherapy (including the anti-B-cell monoclonal antibody rituximab if it is a B-cell tumour).

The incidence of a number of other cancers induced by viruses is also increased in HIV-infected people (Box 12.14). Regular cytological examination of the cervix, and of the anus in people who practise anal sex, should be performed to detect pre-malignant lesions, which are easier to treat. In general, the incidence of cancers that are not induced by viruses is similar to that in the general population.
Prevention of opportunistic infections

The best way to prevent opportunistic infections is to improve the CD4 count with ART. However, infections continue to occur in the ART era as CD4 counts take time to improve if ART is initiated in patients with profound immune suppression, immune reconstitution on ART is often suboptimal, and CD4 counts may decline because antiretroviral resistance develops.

Preventing exposure

The best method for avoiding infection is to prevent exposure to the infectious agent. This is possible only for a few opportunistic infections, however. Furthermore, many opportunistic infections occur after reactivation of latent/dormant infection after prior exposure; examples include herpes simplex virus, zoster (shingles), CMV, toxoplasmosis, cryptococcosis and the endemic mycoses.

Safe water and food

Cryptosporidiosis, microsporidiosis and cystoisosporiasis may be water-borne. If there is no access to safe water, then water should be boiled before drinking. Food-borne illnesses are also important in HIV infection, notably Salmonella species. Toxoplasma exposure is related to eating raw or undercooked meat. People living with HIV infection need to be informed about food hygiene and the importance of adequately cooked meat.

Tuberculosis

Preventing exposure to tuberculosis is important when there is an infectious case in the household, in clinics and in hospitals. Adequate ventilation, masks and safe coughing procedures reduce the risk of exposure.

Malaria vector control

All HIV-infected individuals living in malarious areas should practise vector control, as malaria occurs more frequently and is more severe in HIV-infected people. The most cost-effective way to achieve this is by using insecticide-impregnated bed nets. Other modalities of vector control that are of benefit to the community, such as reducing standing water and spraying with residual insecticides and larvicides, should also be implemented.

Safer sex

HIV-infected individuals should practise safer sex in order to reduce the transmission of HIV. Even if their partners are HIV-infected, condoms should be used, as HIV mutants that have developed antiretroviral drug resistance can be transmitted. Safer sex will also lower the risk of acquiring herpes simplex virus and human herpesvirus 8.

Pets

Toxoplasma gondii can be acquired from kittens or cat litter, and people living with HIV infection should avoid handling either. Cryptosporidiosis can be transmitted from animals, and patients should be advised to wash their hands after handling animals.

Chemoprophylaxis

Chemoprophylaxis is the use of antimicrobial agents to prevent infections. Primary prophylaxis is used to prevent opportunistic infections that have not yet occurred. Secondary prophylaxis is used to prevent recurrence of opportunistic infections because many may recur after an initial response to therapy (see Box 12.11). Secondary prophylaxis can be discontinued when ART results in immune reconstitution, with CD4 counts increasing to over 200 cells/mm², but for CMV and MAC, prophylaxis can be stopped if CD4 counts increase to more than 100 cells/mm².

Co-trimoxazole primary prophylaxis

Co-trimoxazole reduces the incidence of a number of opportunistic infections (Box 12.15), resulting in lower hospitalisation and mortality rates. The indications for initiating co-trimoxazole are either clinical evidence of immune suppression (WHO clinical stages 3 or 4) or laboratory evidence of immune suppression (CD4 count <200 cells/mm³). In low-income countries where malaria and/or severe bacterial infections are highly prevalent, the WHO recommends initiating co-trimoxazole regardless of CD4 counts or clinical stage. The recommended dose of co-trimoxazole is 960 mg daily, but trials have shown that half this dose is as effective and may be associated with less toxicity. Co-trimoxazole prophylaxis can be discontinued when CD4 counts increase to more than 200 cells/mm³ on ART, except in low-income countries where it should be continued life-long.

Co-trimoxazole prophylaxis is well tolerated. The most common side-effect is hypersensitivity, causing a maculo-papular rash. If therapy is discontinued, desensitisation or rechallenge under antihistamine cover should be attempted, unless the rash was accompanied by systemic symptoms or mucosal involvement. Prophylactic doses of co-trimoxazole can also cause neutropenia, but this is very uncommon and routine monitoring of blood counts is not necessary. If co-trimoxazole cannot be tolerated, then

Tuberculosis preventive therapy

Trials in patients not on ART showed that preventive therapy, either with isoniazid or combinations of rifamycins with isoniazid, reduces the risk of tuberculosis only in HIV-infected patients with a positive tuberculin skin test. In HIV infection, induration of 5 mm or more on a Mantoux test is regarded as positive. Recent evidence indicates that tuberculin skin tests do not predict benefit in patients starting ART or established on ART in high tuberculosis prevalence settings.

There is no CD4 count or clinical threshold for starting or stopping tuberculosis preventive therapy. It is important to rule out active tuberculosis before starting preventive therapy, and symptom screening has been shown to be adequate to achieve this (Box 12.16). The usual duration of isoniazid preventive therapy is 6 months but this does not provide long-term reduction in the risk of tuberculosis. Isoniazid for 36 months has been shown to be much more effective in people with a positive tuberculin skin test. Rifampicin or rifapentine combined with isoniazid for 12 weeks has been shown to be at least as effective as 6–12 months of isoniazid.

Mycobacterium avium complex prophylaxis

In high-income countries, a macrolide (azithromycin or clarithromycin) is recommended to prevent MAC in patients with a CD4 count below 50 cells/mm³, which can be discontinued once the CD4 count has risen to over 100 cells/mm³ on ART. MAC is uncommon in low- and middle-income countries and primary prophylaxis is thus not warranted.

Preventing cryptococcosis

Serum cryptococcal antigen test should be done in patients with a CD4 count below 100 cells/mm³. If this is positive, pre-emptive therapy with fluconazole should be commenced.

Immunisation

There are significant problems associated with vaccination in HIV infection. Firstly, vaccination with live organisms is contraindicated in patients with severe immune suppression, as this may result in disease from the attenuated organisms. Secondly, immune responses to vaccination are impaired in HIV-infected patients. If the CD4 count is below 200 cells/mm³, then immune responses to immunisation are very poor. Therefore it is preferable to wait until the CD4 count has increased to more than 200 cells/mm³ on ART before immunisation is given, and essential if live virus vaccines are used. All patients should be given a conjugate pneumococcal vaccine and annual influenza vaccination. Hepatitis B vaccination should be given to those who are not immune. In the UK, the following additional vaccines are also recommended:
- hepatitis A: in those at risk
- human papillomavirus: in people <40 years old
- measles, mumps and rubella (MMR): in those with negative measles serology
- meningococcus: in people <25 years old, those with asplenia or complement deficiency, during outbreaks
- diphtheria/tetanusacellular pertussis (dTaP)/inactivated poliovirus vaccine (IPV): meeting general indications
- chickenpox: if seronegative; those who are seropositive should receive the shingles vaccine.

Bacille Calmette–Guérin (BCG) is contraindicated in all HIV-infected people.

Antiretroviral therapy

ART has transformed HIV from a progressive illness with a fatal outcome into a chronic manageable disease with a near-normal life expectancy.

The goals of ART are to:
- reduce the viral load to an undetectable level for as long as possible
- improve the CD4 count to over 200 cells/mm³ so that severe HIV-related disease is unlikely
- improve the quantity and quality of life without unacceptable drug toxicity
- reduce HIV transmission.

Many of the antiretroviral drugs that were initially used have largely been abandoned because of toxicity or poor efficacy. The drugs that are currently recommended are shown in Box 12.17, and their targets in the HIV life cycle in Figure 12.1.

Selecting antiretroviral regimens

The standard combination antiretroviral regimens are two NRTIs together with an NNRTI, protease inhibitor (PI) or integrase inhibitor. Dual NRTI combinations are usually emtricitabine or lamivudine (they have the same mechanism of action and so are never combined), together with one of abacavir, tenofovir or zidovudine. It is possible to construct effective regimens without NRTIs if there is intolerance or resistance to the NRTIs. Currently used PIs should always be administered with ritonavir, which

*These drugs are no longer recommended as first-line options in high-income countries due to their toxicity.
itself is a PI that is toxic in therapeutic doses. Low doses of ritonavir dramatically increase the concentrations and elimination half-lives of other PIs by inhibiting the efflux pump P-glycoprotein and the cytochrome P450 isoenzyme CYP3A.

Most guidelines from high-income countries, including the UK, allow clinicians to choose a starting regimen of dual NRTIs combined with an NNRTI, or a PI or an integrase inhibitor, as these three regimens have similar efficacy. Subsequent ART regimen switches for virological failure are guided by the results of resistance testing (see below). For low- and middle-income countries, the WHO recommends a public health approach to using ART with standardised first-line (NNRTI plus dual NRTIs) and second-line (ritonavir-boosted PI plus dual NRTIs) regimens. NNRTIs are preferred by the WHO in first-line regimens, as they are cheaper than PIs and better tolerated. Furthermore, NNRTIs need to be given with two fully active NRTIs because they have a low genetic barrier to resistance (see below), whereas PI-containing regimens are effective even when there are some mutations conferring resistance to the NRTIs. PIs in second-line regimens are therefore preferable in settings where resistance testing is not widely available. The public health approach to using ART can be implemented by nurses and has been successfully applied in resource-poor settings.

Criteria for starting ART

Guidelines now recommend starting ART in all people with confirmed HIV infection, irrespective of CD4 count or clinical status. Early initiation of ART, compared with the previous strategy of deferring ART until CD4 thresholds or clinical disease occurs, has been shown to reduce morbidity and mortality, and has the additional benefit of reducing the risk of transmission.

It is seldom necessary to start ART urgently. Several consultations are required to give patients insight into the need for life-long ART, to stress the importance of adherence and to formulate a personal treatment plan. Disclosure of HIV status, joining support groups and using patient-nominated treatment supporters should be encouraged, as these have been shown to improve adherence. Recognition and management of depression and substance abuse is also important.

In patients with major opportunistic infections, ART should generally be started within 2 weeks, with two important exceptions: in cryptococcal meningitis, ART should be deferred for 5 weeks, as earlier initiation increases the risk of death; and in tuberculosis, ART should be deferred until 8 weeks (except if the CD4 count is <50 cells/mm³), as earlier initiation increases the risk of the immune reconstitution inflammatory syndrome (see below).

Monitoring efficacy

The most important measure of ART efficacy is the viral load. A baseline viral load should be measured prior to initiating treatment. Viral load measurement should be repeated 4 weeks after starting ART, when there should be at least a 10-fold decrease. The viral load should be suppressed after 6 months. Once the viral load is suppressed, measurement should be repeated 6-monthly. Failure of ART is defined by the viral load becoming detectable after suppression. In most guidelines, a viral load threshold is used to define virological failure, e.g. more than 200 (UK) or more than 1000 (WHO) copies/mL. Adherence support should be enhanced if virological failure is detected, and measurement of the viral load repeated to confirm failure before switching to a new ART regimen.

CD4 counts are generally monitored every 6 months together with the viral load, but there is little point in repeating the CD4 count in patients who maintain virological suppression and whose CD4 count is >350 cells/mm³. The CD4 count increases rapidly in the first month, followed by a more gradual increase. In the first year, the CD4 count typically increases by 100–150 cells/mm³, and about 80 cells/mm³ per annum thereafter until the reference range is reached, provided the viral load is suppressed. However, CD4 responses are highly variable: in about 15–30% of patients the CD4 count does not increase despite virological suppression, and in a similar proportion of patients the CD4 response is good despite the presence of virological failure. If ART is stopped, the CD4 count rapidly falls to the baseline value before ART was commenced.

Antiretroviral resistance

Reverse transcription is error-prone, generating a large number of mutations. If the viral load is suppressed on ART, viral replication is suppressed and resistance mutations will not be selected. If ART is taken and there is ongoing replication, due to either resistant mutations or suboptimal adherence, mutations conferring resistance to antiretroviral drugs will be selected. Antiretroviral drugs differ in their ability to select for resistant mutations. Some drugs (e.g. emtricitabine, lamivudine, efavirenz) have a low genetic barrier to resistance, rapidly selecting for a single mutation conferring high-level resistance. PIs and some NRTIs (e.g. zidovudine) select for resistance mutations slowly, and multiple resistant mutations often need to accumulate before the drug’s efficacy is lost. Patients who develop antiretroviral resistance may transmit resistant virus to others and will eventually develop clinical failure.

Antiretroviral resistance is assessed by sequencing the relevant viral genes to detect mutations that are known to confer resistance. The patient must be taking ART when the test is performed, as otherwise the wild-type virus will predominate and resistant mutations will not be detected. The resistant proviral DNA is archived in latent CD4 cells and will re-emerge rapidly on re-exposure to the antiretroviral. In regions where resistance testing is affordable, it is recommended at baseline (to detect primary resistance) and at every confirmed virological failure, in order to select the most appropriate antiretrovirals in a new regimen.

ART complications

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a common early complication of ART, especially in patients who start ART with CD4 counts below 50 cells/mm³. IRIS presents either with paradoxical deterioration of an existing opportunistic disease (including infections that are responding to appropriate therapy) or with the unmasking of a new infection. The clinical presentation of IRIS events is often characterised by an exaggerated immune response, with pronounced inflammatory features. For example, patients with CMV retinitis developing IRIS on ART develop a uveitis; inflammatory haloes occur around KS lesions. Paradoxical tuberculosis iritis is common but it is important to exclude multidrug resistance, which could be responsible for the deterioration. IRIS is associated with a mortality of around 5% but this is higher when it complicates CNS infections.
The management of IRIS is to continue ART and to ensure that the opportunistic disease is adequately treated. Symptomatic treatments are helpful. Glucocorticoids are often used for more severe IRIS manifestations but they should not be given to patients with KS, as this can result in rapid progression of KS lesions.

### Lipodystrophy

Long-term use of ART is associated with changes in body fat distribution called lipodystrophy, which can present either with fat accumulation (e.g. visceral fat, ‘buffalo hump’) or with subcutaneous fat loss (‘lipoatrophy’, Fig. 12.16), or with both fat loss and accumulation. The thymidine analogue NRTIs ( stavudine and, to a lesser extent, zidovudine) are associated with fat loss. Switching to the non-thymidine NRTIs, abacavir or tenofovir, will result in very gradual improvement of lipoatrophy.

Previously, PIs were thought to be the cause of fat accumulation. However, recent studies have shown that all classes of antiretrovirals are associated with fat gain to a similar extent, and visceral adiposity is similar to that seen in the general population. Although not yet fully resolved, the current weight of evidence is that fat gain on ART is a return to normal by treating HIV infection.

### Hypersensitivity rashes

These are common but must be differentiated from the other causes described on page 314. The NRTI abacavir typically causes a systemic hypersensitivity reaction, which is limited to people with HLA-B*5701, about 50% of whom will develop a hypersensitivity reaction. HLA testing should be done before abacavir is given and the drug should not be prescribed for people who are HLA-B*5701-positive, which is rare in people of African descent. Rechallenge must never be attempted after abacavir hypersensitivity, as fatal reactions may occur.

Drug rashes are very common with NNRTIs. When the NNRTI rash is mild and not accompanied by systemic involvement, the suspected drug is often continued and antihistamines are administered. The rash usually resolves. If it worsens or if systemic features develop, the NNRTI should be discontinued.

### Other adverse effects

The NNRTI efavirenz causes insomnia, agitation, euphoria or dysphoria in many patients but tolerance to its neuropsychiatric effects develops in a few weeks in most patients. The NRTI zidovudine can cause anaemia and neutropenia, and tenofovir may cause nephrotoxicity and loss of bone mineral density. Some PIs are associated with dyslipidaemias and may increase the risk of myocardial infarction.

### ART in special situations

#### Pregnancy

All pregnant women should have HIV testing at an early stage in pregnancy. The CD4 count falls by about 25% during pregnancy due to haemodilution. The course of HIV disease progression is not altered by pregnancy. In the pre-ART era, the rate of mother-to-child transmission was 15–40%, with rates being influenced by several factors (see Box 12.3).

ART has dramatically reduced the risk of mother-to-child transmission of HIV to less than 1%. All pregnant women should start ART at the beginning of the second trimester, unless they have advanced disease, when ART should be started in the first trimester.

Caesarean section is associated with a lower risk of mother-to-child transmission than vaginal delivery, but the mode of delivery does not affect transmission risk if the viral load is suppressed on ART.

HIV is also transmitted by breastfeeding. In high-income countries, exclusive formula feeding is generally recommended. In resource-poor settings, however, formula feeding is associated with a risk of infant morbidity and mortality, which may negate the benefit of not transmitting HIV to the infant. There is minimal risk of transmitting HIV by breastfeeding in women with a suppressed viral load on ART. Furthermore, providing antiretrovirals to infants (usually nevirapine monotherapy) while they are breastfeeding has been shown to reduce the risk of transmission. Breastfeeding is therefore now encouraged in resource-poor settings. Infants should be exclusively breastfed for the first 6 months, as mixed
feeding (with formula or solids) is associated with a higher risk of transmission.

Diagnosis of HIV in infancy requires the detection of HIV RNA by PCR, as maternal antibodies to HIV, which persist for up to 15 months, will give a false-positive result on antibody assays. PCR should ideally be carried out within 6 weeks of birth to facilitate early ART initiation. If the baby is breastfed, the PCR should be repeated 2 weeks after weaning.

**Prevention of HIV**

An effective HIV vaccine remains elusive due to the extensive genetic diversity of HIV and the lack of a safe attenuated virus. Measures for the prevention of HIV transmission are shown in Box 12.19.

### Pre-exposure prophylaxis

Pre-exposure prophylaxis (PrEP) with daily tenofovir plus emtricitabine has been shown to reduce the risk of HIV acquisition in people at ongoing high risk (e.g. from sex or injecting drug use) and is well tolerated. Regular HIV testing should be done in people on PrEP.

### Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) is recommended when the risk is deemed to be significant after a careful risk assessment, in both occupational and non-occupational settings. The first dose should be given as soon as possible, preferably within 6–8 hours. There is no point in starting PEP after 72 hours. Tenofovir together with emtricitabine is the most widely used dual NRTI combination, together with either a PI or an integrase inhibitor. PEP should not be given if the exposed person is HIV-infected. HIV antibody testing should be performed at 3 months after exposure.

**Clinical examination in men**

1. **Inguinal glands**
   - Significant enlargement

2. **Skin around groin and scrotum**
   - Warts
   - Tinea cruris

3. **Pubic area**
   - *Pthirus pubis* (crab louse)

4. **Scrotal contents**
   - Abnormal masses or tenderness (epididymo-orchitis)

5. **Skin of penis**
   - (Retract prepuce if present)
   - Genital warts
   - Ulcers
   - Be aware of normal anatomical features such as coronal papillae, or prominent sebaceous or parafrenal glands

6. **Urethral meatus**
   - Discharge

7. **Perianal area**
   - (Men who have sex with men, and heterosexual men)
   - Warts

8. **Rectum**
   - (Men who have sex with men practising receptive anal intercourse)
   - Proctoscope
   - Proctitis

**Observation**
- Mouth
- Eyes
- Joints
- Skin:
  - Rash of secondary syphilis
  - Scabies
  - Manifestations of HIV infection (Ch. 12)

**Investigations for STIs in heterosexual males**
- **First-void urine (FVU)** is the specimen of choice for the combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia
- Alternatively, for gonorrhoea, a urethral swab plated directly on a selective medium such as modified New York City (MNYC), or sent in an appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Serological test for syphilis (STS), e.g. enzyme immunoassay (EIA) for antitreponemal immunoglobulin G (IgG) antibody
- Human immunodeficiency virus (HIV) test (see note)

**Investigations for STIs in men who have sex with men**
- **FVU**, and pharyngeal and rectal swabs for combined NAAT for gonorrhoea and chlamydia
- STS (repeat testing may be necessary in the event of negative test results in the first few weeks following exposure)
- Serological tests for hepatitis A/B (with a view to vaccination if seronegative)
- HIV test (see note)

*A urethral swab can be submitted if the patient is unable to pass urine.

**HIV testing**
It should always be standard practice to offer HIV testing as part of screening for sexually transmitted infection (STI) because the benefits of early diagnosis outweigh other considerations. Extensive pre-test counselling is not required in most instances, but it is important to establish efficient pathways for referral of patients at high risk for whom the clinician wishes specialist support, and for those diagnosed as HIV-positive.
Clinical examination in women

**4 Labia majora and minora**
- Ulcers
- Vulvitis

**3 Pubic area**

**2 Inguinal glands**
- Significant enlargement

**1 Abdomen**
- Abnormal masses or tenderness

**6 Vagina and cervix**
- Abnormal discharge
- Warts
- Ulcers
- Inflammation
- In women with lower abdominal pain, bimanual examination for adnexal tenderness (pelvic inflammatory disease)

**5 Perineum and perianal skin**
- Warts
- Ulcers

**Observation**
- Mouth
- Eyes
- Joints
- Skin:
  - Rash of secondary syphilis
  - Scabies
  - Manifestations of HIV infection (Ch. 12)

**Investigations for STIs in women**
- Self-taken vaginal swab, or clinician-obtained cervical or vaginal swab, for combined NAAT for gonorrhoea and chlamydia
- Alternatively, for gonorrhea, cervical and urethral swabs plated directly on a selective medium such as MNYC, or sent in appropriate transport medium, can be cultured to allow for assessment of antimicrobial sensitivities
- Wet mount for microscopy or high vaginal swab (HVS) for culture of *Trichomonas*
- STS, e.g. EIA for antitreponemal IgG antibody
- HIV test (see note)

**Management goals in suspected STI**
- Relief of any symptoms
- Screening for treatable STI that may not be causing symptoms
- Tracing and treatment of sexual contacts who may also be infected
- Advice to reduce risk of infection in the future

**Those at particular risk from STIs**
- Sex workers, male and female
- Clients of sex workers
- Men who have sex with men
- Injecting drug users (sex for money or drugs) and their partners
- Frequent travellers

*Adapted from WHO/UNAIDS, 1997.*
SEXUALLY TRANSMITTED INFECTIONS

Sexually transmitted infections (STIs) are a group of contagious conditions whose principal mode of transmission is by intimate sexual activity involving the moist mucous membranes of the penis, vulva, vagina, cervix, anus, rectum, mouth and pharynx, along with their adjacent skin surfaces. A wide range of infections may be sexually transmitted, including syphilis, gonorrhoea, human immunodeficiency virus (HIV), genital herpes, genital warts, chlamydia and trichomoniasis. Bacterial vaginosis and genital candidiasis are not regarded as STIs, although they are common causes of vaginal discharge in sexually active women. Chancroid, lymphogranuloma venereum (LGV) and granuloma inguinale are usually seen in tropical countries. Hepatitis viruses A, B, C and D (p. 871) may be acquired sexually, as well as by other routes. Although primarily transmitted by mosquito bite, cases of male-to-female sexual transmission of Zika virus have been described and the virus is known to persist in semen for several months (p. 247).

The World Health Organization (WHO) estimates that 357 million curable STIs (Trichomonas vaginalis, Chlamydia trachomatis, gonorrhoea and syphilis) occur worldwide each year. In the UK in 2014, the most common treatable STIs diagnosed were chlamydia (220,000 cases) and gonorrhoea (nearly 40,000 cases). Genital warts are the second most common complaint seen in genitourinary medicine (GUM) departments. In addition to causing morbidity themselves, STIs may increase the risk of transmitting or acquiring HIV infection (Ch. 12).

As coincident infection with more than one STI is seen frequently, GUM clinics routinely offer a full set of investigations at the patient’s first visit (pp. 330–331), regardless of the reason for attendance. In other settings, less comprehensive investigation may be appropriate.

The extent of the examination largely reflects the likelihood of HIV infection or syphilis. Most heterosexuals in the UK are at such low risk of these infections that routine extragenital examination is unnecessary. This is not the case in parts of the world where HIV is endemic, or for men who have sex with men (MSM) in the UK. In other words, the extent of the examination is determined by the sexual history (Box 13.1).

Approach to patients with a suspected STI

Patients concerned about the possible acquisition of an STI are often anxious. Staff must be friendly, sympathetic and reassuring; they should have the ability to put patients at ease, while emphasising that clinic attendance is confidential. The history focuses on genital symptoms, with reference to genital ulceration, rash, irritation, pain, swelling and urinary symptoms, especially dysuria. In men, the clinician should ask about urethral discharge, and in women, vaginal discharge, pelvic pain or dyspareunia. Enquiry about general health should include menstrual and obstetric history, cervical cytology, recent medication, especially with antimicrobial or antiviral agents, previous STI and allergy. Immunisation status for hepatitis A and B should be noted, as should information about alcohol intake and recreational drug use. Some MSM use new psychoactive substances (NPS), formerly referred to in the UK as ‘legal highs’, to enhance their sexual experience. Often described as ‘chemsex’, this has been associated with outbreaks of infections including syphilis, LGV and hepatitis C.

A detailed sexual history is imperative (Box 13.1), as this informs the clinician of the degree of risk for certain infections, as well as specific sites that should be sampled; for example, rectal samples should be taken from men who have had unprotected anal sex with other men. Sexual partners, whether male or female, and casual or regular, should be recorded. Sexual practices – insertive or receptive vaginal, anal, orogenital or oroanal – should be noted, as should choice of contraception for women, and condom use for both sexes.

### STI during pregnancy

Many STIs can be transmitted from mother to child in pregnancy, either transplacentally or during delivery. Possible outcomes are highlighted in Box 13.2.

### STI in children

The presence of an STI in a child may be indicative of sexual abuse, although vertical transmission may explain some presentations in the first 2 years. In an older child and in adolescents, STI may

### 13.1 How to take a sexual history

- In your lifetime, have your sexual partners been male, female or both?
- Do you have a regular sexual partner at present?
- If yes:
  - How long have you been together?
  - When did you last have sex with anyone else?
- If no:
  - When did you last have sex?
  - Was this a regular or a casual partner?
- D/did you use a condom?
be the result of voluntary sexual activity. Specific issues regarding the management of STI and other infections in adolescence are discussed in Box 11.25 (p. 235).

Presenting problems in men

Urethral discharge

In the UK the most important causes of urethral discharge are gonorrhoea and chlamydia. In a significant minority of cases, tests for both of these infections are negative, a scenario often referred to as non-specific urethritis (NSU). Some of these cases may be caused by Trichomonas vaginalis, herpes simplex virus (HSV), mycoplasmas, ureaplasmas or adenoviruses. A small minority seem not to have an infectious aetiology.

Gonococcal urethritis usually causes symptoms within 7 days of exposure. The discharge is typically profuse and purulent. Chlamydial urethritis has an incubation period of 1–4 weeks, and tends to result in milder symptoms than gonorrhoea; there is overlap, however, and microbiological confirmation should always be sought.

Investigations

A presumptive diagnosis of urethritis can be made from a Gram-stained smear of the urethral exudate (Fig. 13.1), which will demonstrate significant numbers of polymorphonuclear leucocytes (≥5 per high-power field). A working diagnosis of gonococcal urethritis is made if Gram-negative intracellular diplococci (GNDC) are seen; if no GNDC are seen, a label of non-gonococcal, non-chlamydial urethritis is applied.

If microscopy is not available, urine samples and/or swabs should be taken and empirical antimicrobials prescribed. A first-void urine (FVU) sample should be submitted for a combined nucleic acid amplification test (NAAT) for gonorrhoea and chlamydia; a urethral swab is an alternative if the patient cannot pass urine. When gonorrhoea is suspected, a urethral swab should be sent for culture and antimicrobial sensitivities of Neisseria gonorrhoeae. Tests for other potential causes of urethritis are not performed routinely.

A swab should also be taken from the pharynx because gonococcal infection here is not reliably eradicated by single-dose therapy. In MSM, swabs for gonorrhoea and chlamydia should be taken from the rectum.

Management

This depends on local epidemiology and the availability of diagnostic resources. Treatment is often presumptive, with prescription of multiple antimicrobials to cover the possibility of gonorrhoea and/or chlamydia. This is likely to include a single-dose treatment for gonorrhoea, which is desirable because it eliminates the risk of non-adherence. The recommended agents for treating gonorrhoea vary according to local antimicrobial resistance patterns (p. 340). Appropriate treatment for chlamydia (p. 340) should also be prescribed because concurrent infection is present in up to 50% of men with gonorrhoea. Non-gonococcal, non-chlamydial urethritis is treated as for chlamydia.

Patients should be advised to avoid sexual contact until it is confirmed that any infection has resolved and, whenever possible, recent sexual contacts should be traced. The task of contact tracing – also called partner notification – is best performed by trained nurses based in GUM clinics; it is standard practice in the UK to treat current sexual partners of men with gonococcal or non-specific urethritis without waiting for microbiological confirmation.

If symptoms clear, a routine test of cure is not necessary, but patients should be re-interviewed to confirm that there was no immediate vomiting or diarrhoea after treatment, that there has been no risk of reinfection, and that traceable partners have sought medical advice.

Genital itch and/or rash

Patients may present with many combinations of penile/genital symptoms, which may be acute or chronic, and infectious or non-infectious. Box 13.3 provides a guide to diagnosis.

Balanitis refers to inflammation of the glans penis, often extending to the under-surface of the prepuce, in which case it is called balanoposthitis. Tight prepuce and poor hygiene may be aggravating factors. Candidiasis is sometimes associated with immune deficiency, diabetes mellitus, and the use of broad-spectrum antimicrobials, glucocorticoids or antimitotic drugs. Local saline bathing is usually helpful, especially when no cause is found.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the glans, coronal sulcus or shaft of penis (Fig. 13.2), but solitary lesions occur rarely. Perianal ulcers may be seen in MSM. The diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by polymerase chain reaction (PCR). Increasingly, laboratories will also test for Treponema pallidum by PCR.

In the UK, the possibility of syphilis or any other ulcerating STI is much less likely unless the patient is an MSM and/or has had a sexual partner from a region where tropical STIs are more common. The classic lesion of primary syphilis (chancre) is single, painless and indurated; however, multiple lesions are seen rarely and anal chancres are often painful. Diagnosis is made in GUM clinics by dark-ground microscopy and/or PCR on a swab from a chancre, but in other settings by serological tests for syphilis (p. 338). Other rare infective causes seen in the UK include varicella zoster virus (p. 238) and trauma with secondary infection. Tropical STIs, such as chancroid,
LGV and granuloma inguinale, are described in Box 13.12 (p. 341). Inflammatory causes include Stevens–Johnson syndrome (pp. 1224 and 1254), Behçet’s disease (p. 1043) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma and erythroplasia of Queyrat (intra-epidermal carcinoma), should be considered.

### Genital lumps

The most common cause of genital ‘lumps’ is warts (p. 342). These are classically found in areas of friction during sex, such as the parafrenal skin and prepuce of the penis. Warts may also be seen in the urethral meatus, and less commonly on the shaft or around the base of the penis. Perianal warts are surprisingly common in men who do not have anal sex.

The differential diagnosis includes molluscum contagiosum and skin tags. Adolescent boys may confuse normal anatomical features such as coronal papillae (p. 330), parafrenal glands or sebaceous glands (Fordyce spots) with warts.

### Proctitis in men who have sex with men

STIs that may cause proctitis in MSM include gonorrhoea, chlamydia, herpes and syphilis. The substrains of *Chlamydia trachomatis* that cause LGV (L1–3) have been associated with outbreaks of severe proctitis in Northern Europe, including the UK. Symptoms include mucopurulent anal discharge, rectal bleeding, pain and tenesmus.
Vaginal discharge

The natural vaginal discharge may vary considerably, especially under differing hormonal influences such as puberty, pregnancy or prescribed contraception. A sudden or recent change in discharge, especially if associated with alteration of colour and/or smell, or vulval itch/irritation, is more likely than a gradual or long-standing change to indicate an infective cause.

Local epidemiology is particularly important when assessing possible causes. In the UK, most cases of vaginal discharge are not sexually transmitted, being due to either candidal infection or bacterial vaginosis (BV). Worldwide, the most common treatable STI causing vaginal discharge is trichomoniasis; other possibilities include gonorrhoea and chlamydia. HSV may cause increased discharge, although vulval pain and dysuria are usually the predominant symptoms. Non-infective causes include retained tampons, malignancy and/or fistulae.

Speculum examination often allows a relatively accurate diagnosis, with appropriate treatment to follow (Box 13.4). If the discharge is homogeneous and off-white in colour, vaginal pH is greater than 4.5, and Gram stain microscopy reveals scanty or absent lactobacilli with significant numbers of Gram-variable organisms, some of which may be coating vaginal squamous cells (so-called Clue cells, Fig. 13.3), the likely diagnosis is BV. If there is vulval and vaginal erythema, the discharge is curdy in nature, vaginal pH is less than 4.5, and Gram stain microscopy reveals fungal spores and pseudohyphae, the diagnosis is candidiasis. Trichomoniasis tends to cause a profuse yellow or green discharge and is usually associated with significant vulvovaginal inflammation. Diagnosis is made by observing motile flagellate protozoa on a wet-mount microscopy slide of vaginal material and/or by culture.

If examination reveals the discharge to be cervical in origin, the possibility of chlamydial or gonococcal infection is increased and appropriate cervical or vaginal swabs should be taken (p. 331). In addition, Gram stain of cervical and urethral material may reveal GNDC, allowing presumptive treatment for gonorrhoea to be given. If gonococcal cervicitis is suspected, swabs should also be taken from the pharynx and rectum; infections at these sites are not reliably eradicated by single-dose therapy and a test of cure will therefore be required.

GUM clinics in the UK may offer sexually active women presenting with vaginal discharge an STI screen (p. 331). In other settings, such as primary care or gynaecology, testing for chlamydia and gonorrhoea may be considered in young women (<25 years old), those who have changed partner recently, and those not using a barrier method of contraception, even if a non-STI cause of discharge is suspected clinically.

Treatment of infections causing vaginal discharge is shown in Box 13.4.
Lower abdominal pain

Pelvic inflammatory disease (PID, infection or inflammation of the Fallopian tubes and surrounding structures) is part of the extensive differential diagnosis of lower abdominal pain in women, especially those who are sexually active. The possibility of PID is increased if, in addition to acute/subacute pain, there is dyspareunia, abnormal vaginal discharge and/or bleeding. There may also be systemic features, such as fever and malaise. On examination, lower abdominal pain is usually bilateral, and vaginal examination reveals adnexal tenderness with or without cervical excitation. Unfortunately, a definitive diagnosis can only be made by laparoscopy. A pregnancy test should be performed (as well as the diagnostic tests on p. 331) because the differential diagnosis includes ectopic pregnancy.

Broad-spectrum antibiotics, including those active against gonorrhoea and chlamydia, such as ofloxacin and metronidazole, should be prescribed if PID is suspected, along with appropriate analgesia. Delaying treatment increases the likelihood of adverse sequelae, such as abscess formation, and tubal scarring that may lead to ectopic pregnancy or infertility. Hospital admission may be indicated for severe symptoms.

Genital ulceration

The most common cause of ulceration is genital herpes. Classically, multiple painful ulcers affect the introitus, labia and perineum, but solitary lesions occur rarely. Inguinal lymphadenopathy and systemic features, such as fever and malaise, are more common than in men. Diagnosis is made by gently scraping material from lesions and sending this in an appropriate transport medium for culture or detection of HSV DNA by PCR. Increasingly, laboratories will also test such samples for Treponema pallidum by PCR. In the UK, the possibility of any other ulcerating STI is unlikely unless the patient has had a sexual partner from a region where tropical STIs are more common (see Box 13.12).

Inflammatory causes include lichen sclerosus, Stevens–Johnson syndrome (pp. 1224 and 1254), Behçet’s disease (p. 1043) and fixed drug reactions. In older patients, malignant and pre-malignant conditions, such as squamous cell carcinoma, should be considered.

Genital lumps

The most common cause of genital ‘lumps’ is warts. These are classically found in areas of friction during sex, such as the fourchette and perineum. Perianal warts are surprisingly common in women who do not have anal sex.

The differential diagnosis includes molluscum contagiosum, skin tags, and normal papillae or sebaceous glands.

Chronic vulval pain and/or itch

Women may present with a range of chronic symptoms that may be intermittent or continuous (Box 13.5).

Recurrent candidiasis may lead to hypersensitivity to candidal antigens, with itch and erythema becoming more prominent than increased discharge. Effective treatment may require regular oral antifungals, e.g. fluconazole 150 g once a week, plus a combined antifungal/glucocorticoid cream.

Prevention of STI

Case-finding

Early diagnosis and treatment facilitated by active case-finding will help to reduce the spread of infection by limiting the period of infectivity; tracing and treating sexual partners will also reduce the risk of reinfection. Unfortunately, the majority of individuals with an STI are asymptomatic and therefore unlikely to seek medical attention. Improving access to diagnosis in primary care or non-medical settings, especially through opportunistic testing, may help. However, the impact of medical intervention through improved access alone is likely to be small.

Changing behaviour

The prevalence of STIs is driven largely by sexual behaviour. Primary prevention encompasses efforts to delay the onset of sexual activity and limit the number of sexual partners thereafter. Encouraging the use of barrier methods of contraception will also help to reduce the risk of transmitting or acquiring STIs.
is especially important in the setting of ‘sexual concurrency’, where sexual relationships overlap.

Unfortunately, there is contradictory evidence as to which (if any) interventions can reduce sexual activity. Knowledge alone does not translate into behaviour change, and broader issues, such as poor parental role modelling, low self-esteem, peer group pressure in the context of the increased sexualisation of our societies, gender power imbalance and homophobia, all need to be addressed. Throughout the world there is a critical need to enable women to protect themselves from undisciplined and coercive male sexual activity. Economic collapse and the turmoil of war regularly lead to situations where women are raped or must turn to prostitution to feed themselves and their children, and an inability to negotiate safe sex increases their risk of acquiring STI, including HIV.

**Sexually transmitted bacterial infections**

**Syphilis**

Syphilis is caused by infection, through abrasions in the skin or mucous membranes, with the spirochaete *Treponema pallidum*. In adults the infection is usually sexually acquired; however, transmission by kissing, blood transfusion and percutaneous injury has been reported. Transplacental infection of the fetus may occur.

The natural history of untreated syphilis is variable. Infection may remain latent throughout, or clinical features may develop at any time. The classification of syphilis is shown in Box 13.6. All infected patients should be treated. Penicillin remains the drug of choice for all stages of infection.

**Acquired syphilis**

**Early syphilis**

Primary syphilis

The incubation period is usually between 14 and 28 days, with a range of 9–90 days. The primary lesion or chancre (Fig. 13.4) develops at the site of infection, usually in the genital area. A dull red macule develops, becomes papular and then erodes to form an indurated ulcer (chancre). The draining inguinal lymph nodes may become moderately enlarged, mobile, discrete and rubbery. The chancre and the lymph nodes are both painless and non-tender, unless there is concurrent or secondary infection. Without treatment, the chancre will resolve within 2–6 weeks to leave a thin atrophic scar.

---

**Fig. 13.4 Primary syphilis.** A painless ulcer (chancre) is shown in the coronal sulcus of the penis. This is usually associated with inguinal lymphadenopathy. Courtesy of Dr P. Hay, St George’s Hospital, London.

Chanices may develop on the vaginal wall and on the cervix. Extragential chancres are found in about 10% of patients, affecting sites such as the finger, lip, tongue, tonsil, nipple, anus or rectum. Anal chancres often resemble fissures and may be painful.

**Secondary syphilis**

This occurs 6–8 weeks after the development of the chancre, when *Treponema pallidum* disseminate to produce a multisystem disease. Constitutional features, such as mild fever, malaise and headache, are common. Over 75% of patients present with a rash on the trunk and limbs that may later involve the palms and soles; this is initially macular but evolves to maculopapular or papular forms, which are generalised, symmetrical and non-irritable. Scales may form on the papules later. Lesions are red, changing to a ‘gun-metal’ grey as they resolve. Without treatment, the rash may last for up to 12 weeks. Condylomata lata (papules coalescing to plaques) may develop in warm, moist sites such as the vulva or perianal area. Generalised non-tender lymphadenopathy is present in over 50% of patients. Mucosal lesions, known as mucous patches, may affect the genitalia, mouth, pharynx or larynx and are essentially modified papules, which become eroded. Rarely, confluence produces characteristic ‘snail track ulcers’ in the mouth.

Other features, such as meningitis, cranial nerve palsies, anterior or posterior uveitis, hepatitis, gastritis, glomerulonephritis or periostitis, are sometimes seen. Neurological involvement may be more common in HIV-positive patients.

The differential diagnosis of secondary syphilis can be extensive, but in the context of a suspected STI, primary HIV infection is the most important alternative condition to consider (Ch. 12). Non-STI conditions that mimic the rash include psoriasis, pityriasis rosea, scabies, allergic drug reaction, erythema multiforme and pityriasis (tinea) versicolor.

The clinical manifestations of secondary syphilis will resolve without treatment but relapse may occur, usually within the first year of infection. Thereafter, the disease enters the phase of latency.

**Latent syphilis**

This phase is characterised by the presence of positive syphilis serology or the diagnostic cerebrospinal fluid (CSF) abnormalities of neurosyphilis in an untreated patient with no evidence of clinical disease. It is divided into early latency (within 2 years of infection), when syphilis may be transmitted sexually, and late latency, when the patient is no longer sexually infectious.

Transmission of syphilis from a pregnant woman to her fetus, and rarely by blood transfusion, is possible for several years following infection.

**Late syphilis**

Late latent syphilis

This may persist for many years or for life. Without treatment, over 60% of patients might be expected to suffer little or no ill health. Coincidental prescription of antibiotics for other illnesses, such as respiratory tract or skin infections, may treat latent syphilis serendipitously and make the interpretation of serological test results difficult (see below).

Benign tertiary syphilis

This may develop between 3 and 10 years after infection but is now rarely seen in the UK. Skin, mucous membranes, bone, muscle or viscera can be involved. The characteristic feature is a chronic granulomatous lesion called a gumma, which may be single or multiple. Healing with scar formation may impair the function of the structure affected. Skin lesions may take the form of nodules or ulcers, while subcutaneous lesions may ulcerate with a gummy discharge. Healing occurs slowly, with the formation of characteristic tissue-paper scars. Mucosal lesions may occur in the mouth, pharynx, larynx or nasal septum, appearing as punched-out ulcers. Of particular importance is gummatous involvement of the tongue, healing of which may lead to leuoclopakia with the attendant risk of malignant change. Gummata of the tibia, skull, clavicle and sternum have been described, as has involvement of the brain, spinal cord, liver, testis and, rarely, other organs. Resolution of active disease should follow treatment, though some tissue damage may be permanent. Paroxysmal cold haemoglobinuria (p. 950) may be seen.

Cardiovascular syphilis

This may present many years after initial infection. Aortitis, which may involve the aortic valve and/or the coronary ostia, is the key feature. Clinical features include aortic incompetence, angina and aortic aneurysm (p. 505). The condition typically affects the ascending aorta and sometimes the aortic arch; aneurysm of the descending aorta is rare. Treatment with penicillin will not correct anatomical damage and surgical intervention may be required.

Neurosyphilis

This may also take years to develop. Asymptomatic infection is associated with CSF abnormalities in the absence of clinical signs. Meningovascular disease, tabes dorsalis and general paralysis of the insane constitute the symptomatic forms (p. 1125). Neurosyphilis and cardiovascular syphilis may coexist and are sometimes referred to as quaternary syphilis.

### Congenital syphilis

Congenital syphilis is rare where antenatal serological screening is practised. Antisyphilitic treatment in pregnancy treats the fetus, if infected, as well as the mother.

Treponemal infection may give rise to a variety of outcomes after 4 months of gestation, when the fetus becomes immunocompetent:

- miscarriage or stillbirth, prematurely or at term
- birth of a syphilitic baby (a very sick baby with hepatosplenomegaly, bullous rash and perhaps pneumonia)

**Early congenital syphilis (neonatal period)**

- Maculopapular rash
- Condylomata lata
- Mucous patches
- Fissures around mouth, nose and anus
- Rhinitis with nasal discharge (snuffles)
- Hepatosplenomegaly
- Osteochondritis/periostitis
- Generalised lymphadenopathy
- Choroiditis
- Meningitis
- Anaemia/thrombocytopenia

**Late congenital syphilis**

- Benign tertiary syphilis
- Periostitis
- Parovysmal cold haemoglobinuria
- Neurosyphilis
- 8th nerve deafness
- Interstitial keratitis
- Clutton’s joints (painless effusion into knee joints)

**Stigmata**

- Hutchinson’s incisors (anterior–posterior thickening with notch on narrowed cutting edge)
- Mulberry molars (imperfectly formed cusps/deficient dental enamel)
- High arched palate
- Maxillary hypoplasia
- Saddle nose (following snuffles)
- Rhagades (radiating scars around mouth, nose and anus following rash)
- Salt and pepper scars on retina (from choroiditis)
- Corneal scars (from interstitial keratitis)
- Sabre tibia (from periostitis)
- Bossing of frontal and parietal bones (healed periosteal nodes)

- birth of a baby who develops signs of early congenital syphilis during the first few weeks of life (Box 13.7)
- birth of a baby with latent infection who either remains well or develops congenital syphilis/stigmata later in life (see Box 13.7).

### Investigations in adult cases

*Treponema pallidum* may be identified in serum collected from chancres, or from moist or eroded lesions in secondary syphilis using a dark-field microscope, a direct fluorescent antibody test or PCR.

The serological tests for syphilis (STS) are listed in Box 13.8. These are antibody tests that almost always remain positive, even after successful treatment. Prolonged untreated infection results in higher titres that may not decline at all. Interpretation of results requires knowledge of any treatment, which may include antibiotics given coincidentally, e.g. for skin or respiratory tract infections.

Many centres use treponemal enzyme immunoassays (EIAs) for IgG and IgM antibodies to screen for syphilis. EIA for antitreponemal IgM becomes positive at approximately 2 weeks, while non-treponemal tests become positive about 4 weeks after primary syphilis. All positive results in asymptomatic patients must be confirmed by repeat tests.

Biological false-positive reactions occur occasionally; these are most commonly seen with Venereal Diseases Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests (when treponemal tests will be negative). Acute false-positive reactions may be associated with infections, such as infectious mononucleosis, chickenpox and malaria, and may also occur in pregnancy. Chronic false-positive reactions may be associated with autoimmune diseases. False-negative results for non-treponemal tests may be found in secondary syphilis because extremely high antibody levels can...
prevents the formation of the antibody–antigen lattice necessary for the visualisation of the flocculation reaction (the prozone phenomenon).

In benign tertiary and cardiovascular syphilis, examination of CSF should be considered because asymptomatic neurological disease may coexist. The CSF should also be examined in patients with clinical signs of neurosyphilis (p. 1125) and in both early and late congenital syphilis. Positive STS may be found in patients who are being investigated for neurological disease, especially dementia. In many instances, the serology reflects previous infection unrelated to the presenting complaint, especially when titres are low. Examination of CSF is occasionally necessary. Chest X-ray, electrocardiogram (ECG) and echocardiogram are useful in the investigation of cardiovascular syphilis. Biopsy may be required to diagnose gumma.

Endemic treponematoses, such as yaws, endemic (non-veneræal) syphilis (bejel) and pinta (pp. 253 and 254), are caused by treponemes that are morphologically indistinguishable from T. pallidum and cannot be differentiated by serological tests. A VDRL or RPR test may help to elucidate the correct diagnosis because adults with late yaws usually have low titres.

Investigations in suspected congenital syphilis

Passively transferred maternal antibodies from an adequately treated mother may give rise to positive serological tests in her baby. In this situation, non-treponemal tests should become negative within 3–6 months of birth. A positive EIA test for antitreponemal IgM suggests early congenital syphilis. A diagnosis of congenital syphilis mandates investigation of the mother, her partner and any siblings.

Management

Penicillin is the drug of choice. Currently, a single dose of 2.4 megaunits of intramuscular benzathine benzylpenicillin is recommended for early syphilis (≤2 years’ duration), with three doses at weekly intervals being recommended in late syphilis. A 14-day course of procaine penicillin is recommended for the treatment of neurosyphilis, supplemented by a 3-day course of prednisolone (see below). Doxycycline is indicated for patients allergic to penicillin, except in pregnancy (see below). Azithromycin is less favoured due to the potential for resistance. All patients must be followed up to ensure cure, and partner notification is of particular importance. Resolution of clinical signs in early syphilis with declining titres for non-treponemal tests, usually to undetectable levels within 6 months for primary syphilis and 12–18 months for secondary syphilis, is an indicator of successful treatment. Specific treponemal antibody tests may remain positive for life. In patients who have had syphilis for many years there may be little serological response following treatment.

Pregnancy

Penicillin is the treatment of choice in pregnancy. Erythromycin stearate can be given if there is penicillin hypersensitivity, but it crosses the placenta poorly; the newborn baby must therefore be treated with a course of penicillin and consideration given to retreating the mother. Some specialists recommend penicillin desensitisation for pregnant mothers so that penicillin can be given during temporary tolerance. A 10-day course of ceftriaxone is a further alternative. Babies should be treated in hospital with the help of a paediatrician.

Treatment reactions

- **Anaphylaxis.** Penicillin is a common cause; on-site facilities should be available for management (p. 75).
- **Jarisch–Herxheimer reaction.** This is an acute febrile reaction that follows treatment and is characterised by headache, malaise and myalgia; it resolves within 24 hours. It is common in early syphilis and rare in late syphilis. Fetal distress or premature labour can occur in pregnancy.

  The reaction may also cause worsening of neurological (cerebral artery occlusion) or ophthalmic (uveitis, optic neuritis) disease, myocardial ischaemia (inflammation of the coronary ostia) and laryngeal stenosis (swelling of a gumma). Prednisolone 40–60 mg daily for 3 days is recommended to prevent the reaction in patients with these forms of the disease; antisyphilitic treatment can be started 24 hours after introducing glucocorticoids. In high-risk situations it is wise to initiate therapy in hospital.

- **Procaine reaction.** Fear of impending death occurs immediately after the accidental intravenous injection of procaine penicillin and may be associated with hallucinations or fits. Symptoms are short-lived, but verbal assurance and sometimes physical restraint are needed.

  The reaction can be prevented by aspiration before intramuscular injection to ensure the needle is not in a blood vessel.

### Gonorrhoea

Gonorrhoea is caused by infection with Neisseria gonorrhoeae and may involve columnar epithelium in the lower genital tract, rectum, pharynx and eyes. Transmission is usually the result of vaginal, anal or oral sex. Gonococcal conjunctivitis may be caused by accidental infection from contaminated fingers. Untreated mothers may infect babies during delivery, resulting in ophthalmia neonatorum (Fig. 13.5). Infection of children beyond the neonatal period usually indicates sexual abuse.

Clinical features

The incubation period is usually 2–10 days. In men the anterior urethra is commonly infected, causing urethral discharge and dysuria, but symptoms are absent in about 10% of cases. Examination will usually show a mucopurulent or purulent urethral discharge. Rectal infection in MSM is usually asymptomatic but may present with anal discomfort, discharge or rectal bleeding. Proctoscopy may reveal either no abnormality, or clinical evidence of proctitis (p. 334) such as inflamed rectal mucosa and mucopus.

In women, the urethra, paraurethral glands/ducts, Bartholin’s glands/ducts or endocervical canal may be infected. The rectum may also be involved either due to contamination from a urogenital site or as a result of anal sex. Occasionally, the rectum is the
be seen as soon as possible. Delay in treatment may lead to complications (Box 13.10).

Chlamydial infection

Chlamydia is transmitted and presents in a similar way to gonorrhoea; however, urethral symptoms are usually milder and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Complications, such as epididymo-orchitis and sexually acquired reactive arthritis (SARA, p. 1031), are rare.

Sexually transmitted pathogens, such as chlamydia or gonococci, are usually responsible for epididymo-orchitis in men aged less than 35 years, whereas bacteria such as Gram-negative enteric organisms are more commonly implicated in older men.

Treatments for chlamydia are listed in Box 13.11. NSU is treated identically. The partner(s) of men with chlamydia should be treated, even if laboratory tests for chlamydia are negative. Investigation is not mandatory but serves a useful epidemiological purpose; moreover, positive results encourage further attempts at contact-tracing.

Chlamydial infection

Chlamydia is transmitted and presents in a similar way to gonorrhoea; however, urethral symptoms are usually milder and may be absent in over 50% of cases. Conjunctivitis is also milder than in gonorrhoea; pharyngitis does not occur. The incubation period varies from 1 week to a few months. Without treatment, symptoms may resolve but the patient remains infectious for several months. Treatments for chlamydia are listed in Box 13.11. NSU is treated identically. The partner(s) of men with chlamydia should be treated, even if laboratory tests for chlamydia are negative. Investigation is not mandatory but serves a useful epidemiological purpose; moreover, positive results encourage further attempts at contact-tracing.
bleeding from the cervix, evidence of PID or no obvious clinical signs. Treatment options are listed in Box 13.11. The patient’s male partner(s) should be investigated and treated.

Many infections clear spontaneously but others persist. PID, with the risk of tubal damage and subsequent infertility or ectopic pregnancy, is a rare but important long-term complication. Other complications include perihepatitis, chronic pelvic pain, and tender, and there may be nerve root pain in the 2nd and 3rd sacral dermatomes.

Extragenital lesions may develop at other sites, such as the buttock, finger or eye, due to auto-inoculation. Oropharyngeal infection may result from orogenital sex. Complications, such as 3–40 days Ulcers or painful ulcer, 3–10 days Single or multiple painful ulcers with ragged undermined edges, or 3–30 days Small, transient, painless ulcer, vesicle, papule; often unnoticed.

Chancroid, granuloma inguinale and LGV as causes of genital ulcers in the tropics are described in Box 13.12. LGV is also a cause of proctitis in MSM (p. 334).
Analgesia may be required and saline bathing can be soothing. Treatment may be continued for longer than 5 days if new lesions develop. Occasionally, intravenous therapy may be indicated if oral therapy is poorly tolerated or aseptic meningitis occurs.

Catheterisation via the suprapubic route is advisable for urinary retention due to autonomic neuropathy because the transurethral route may introduce HSV into the bladder.

Recurrent genital herpes
Symptomatic recurrences are usually mild and may require no specific treatment other than saline bathing. For more severe episodes, patient-initiated treatment at onset, with one of the following 5-day oral regimens, should reduce the duration of the recurrence:

- aciclovir 200 mg five times daily
- famciclovir 125–250 mg twice daily
- valaciclovir 500 mg twice daily.

In a few patients, treatment started at the onset of prodromal symptoms may abort recurrence.

Suppressive therapy may be required for patients with frequent recurrences, especially if these are experienced at intervals of less than 4 weeks. Treatment should be given for a minimum of 1 year before stopping to assess recurrence rate. About 20% of patients will experience reduced attack rates thereafter, but for those whose recurrences remain unchanged, resumption of suppressive therapy is justified. Aciclovir 400 mg twice daily is most commonly prescribed.

Management in pregnancy
If her partner is known to be infected with HSV, a pregnant woman with no previous anogenital herpes should be advised to protect herself during sexual intercourse because the risk of disseminated infection is increased in pregnancy. Consistent condom use during pregnancy may reduce transmission of HSV. Genital herpes acquired during the first or second trimester of pregnancy is treated with aciclovir as clinically indicated. Although aciclovir is not licensed for use in pregnancy in the UK, there is considerable clinical evidence to support its safety. Third-trimester acquisition of infection has been associated with life-threatening haematogenous dissemination and should be treated with aciclovir.

Vaginal delivery should be routine in women who are symptomless in late pregnancy. Caesarean section is sometimes considered if there is a recurrence at the beginning of labour, although the risk of neonatal herpes through vaginal transmission is very low. Caesarean section is often recommended if primary infection occurs after 34 weeks because the risk of viral shedding is very high in labour.

Human papillomavirus and anogenital warts

Human papillomavirus (HPV) DNA typing has demonstrated over 90 genotypes (p. 1238), of which HPV-6, HPV-11, HPV-16 and HPV-18 most commonly infect the genital tract through sexual transmission. It is important to differentiate between the benign genotypes (HPV-6 and 11) that cause anogenital warts, and genotypes such as 16 and 18 that are associated with dysplastic conditions and cancers of the genital tract but are not a cause of benign warts. All genotypes usually result in subclinical infection of the genital tract rather than clinically obvious lesions affecting penis, vulva, vagina, cervix, perineum or anus.
**Clinical features**

Anogenital warts caused by HPV may be single or multiple, exophytic, papular or flat. Perianal warts (p. 330), while being more common in MSM, are also found in heterosexual men and women. Rarely, a giant condyloma (Buschke–Löwenstein tumour) develops, with local tissue destruction. Atypical warts should be biopsied. In pregnancy, warts may dramatically increase in size and number, making treatment difficult. Rarely, they are large enough to obstruct labour and, in this case, delivery by caesarean section will be required. Uncommonly, perianal transmission of HPV leads to anogenital warts, or possibly laryngeal papillomas, in the neonate.

**Management**

The use of condoms can help prevent the transmission of HPV to non-infected partners, but HPV may affect parts of the genital area not protected by condoms. Vaccination against HPV infection has been introduced and is in routine use in many countries. There are three types of vaccine:

- A *bivalent vaccine* offers protection against HPV types 16 and 18, which account for approximately 75% of cervical cancers in the UK.
- A *quadrivalent vaccine* offers additional protection against HPV types 6 and 11, which account for over 90% of genital warts.
- A *nonovalent vaccine* protects against five additional high-risk types (31, 33, 45, 52 and 58).

All vaccines have been shown to be highly effective in the prevention of cervical intra-epithelial neoplasia in young women, and the quadrivalent and nonovalent vaccines have also been demonstrated to be highly effective in protecting against HPV-associated genital warts. It is currently recommended that HPV vaccination should be administered prior to the onset of sexual activity, typically at age 11–13, in a course of three injections. In the UK, only girls are offered vaccination, but it is possible that vaccination will be extended to MSM in whom HPV transmission is associated with an increased risk of anal cancer. As no vaccine protects against all oncogenic types of HPV, cervical screening programmes will still be necessary.

A variety of treatments are available for established disease, including the following:

- **Podophyllotoxin**, 0.5% solution or 0.15% cream (contraindicated in pregnancy), applied twice daily for 3 days, followed by 4 days’ rest, for up to 4 weeks, is suitable for home treatment of external warts.
- **Imiquimod cream** (contraindicated in pregnancy), applied 3 times weekly (and washed off after 6–10 hours) for up to 16 weeks, is also suitable for home treatment of external warts.
- **Catephen** (an extract of the green tea plant, *Camellia sinensis*) is applied by the patient three times daily for up to 16 weeks.
- **Cryotherapy** using liquid nitrogen to freeze warty tissue is suitable for external and internal warts but often requires repeated clinic visits.
- **Hyfrecation** – electrolfulguration that causes superficial charring – is suitable for external and internal warts. Hyfrecation results in smoke plume, which contains HPV DNA and has the potential to cause respiratory infection in the operator/patient. Masks should be worn during the procedure and adequate extraction of fumes should be provided.
- **Surgical removal** may be used to excise refractory warts, especially pedunculated perianal lesions, under local or general anaesthesia.

**Molluscum contagiosum**

Infection by molluscum contagiosum virus, both sexual and non-sexual, produces fleshy-coloured, umbilicated, hemispherical papules usually up to 5 mm in diameter after an incubation period of 3–12 weeks (Fig. 13.7). Larger lesions may be seen in HIV infection (p. 306). Lesions are often multiple and, once established in an individual, may spread by auto-inoculation. They are found on the genitalia, lower abdomen and upper thighs when sexually acquired. Facial lesions are highly suggestive of underlying HIV infection. Diagnosis is made clinically or very rarely by electron microscopy. Typically, lesions persist for several months before spontaneous resolution occurs. Treatment regimens are therefore cosmetic; they include cryotherapy, hyfrecation, topical applications of 0.15% podophyllotoxin cream (contraindicated in pregnancy) or expression of the central core.

---

**Viral hepatitis**

The hepatitis viruses A–D (p. 871) may be sexually transmitted:

- **Hepatitis A (HAV)**. Insertive oroanal sex, insertive digital sex, insertive anal sex and multiple sexual partners have been linked with HAV transmission in MSM. HAV transmission in heterosexual men and women is also possible through oroanal sex.
- **Hepatitis B (HBV)**. Insertive oroanal sex, anal sex and multiple sexual partners are linked with HBV infection in MSM. Heterosexual transmission of HBV is well documented and commercial sex workers are at particular risk. Hepatitis D (HDV) may also be sexually transmitted.
- **Hepatitis C (HCV)**. Sexual transmission of HCV is well documented in MSM but less so in heterosexuals. Sexual transmission is less efficient than for HBV.

---

*Fig. 13.7* Molluscum contagiosum of the shaft of the penis.

The sexual partner(s) of patients with HAV and HBV should be seen as soon as possible and offered immunisation where appropriate. Patients with HAV should abstain from all forms of unprotected sex until non-infectious. Those with HBV should likewise abstain from unprotected sex until they are non-infectious or until their partners have been vaccinated successfully. No active or passive immunisation is available for protection against HCV but the consistent use of condoms is likely to protect susceptible partners. Active immunisation against HAV and HBV should be offered to susceptible people at risk of infection. Many STI clinics offer HAV immunisation to MSM along with routine HBV immunisation; a combined HAV and HBV vaccine is available.

Clinical examination in biochemical and metabolic disorders

Many biochemical and metabolic disorders are clinically silent or present with non-specific manifestations, and are first detected by laboratory testing. Several abnormalities can be picked up by history and physical examination, however, as summarised below.

**Hyperlipidaemia**
- Atheroma
- Xanthelasma
- Corneal arcus

**Acute hypernatraemia**
- Extra heart sounds
- Dizziness
- Delirium
- Weakness

**Acute hyponatraemia**
- Cerebral oedema
- Vomiting
- Somnolence
- Seizures
- Coma

**Gangliosidosis**
- Cherry-red spot fundus

**Hypervolaemia**
- Extra heart sounds
- Lung crepitations
- Raised jugular venous pressure
- Ankle oedema

**Hypovolaemia**
- Low blood pressure
- Rapid pulse

**Glycogen storage disease**
- Hepatomegaly

**Porphyria**
- Abdominal pain
- Photosensitive rash

**Hyperlipidaemia**
- Tendon xanthoma
- Eruptive xanthoma

**Observation**
- General appearance
- Skin turgor
- Oedema
- Rash
- Eyes

Assessment of volume status and electrolyte disturbances

- Check blood pressure, pulse and jugular venous pressure
- Check skin turgor
- Check for dry mouth
- Check for sacral and ankle oedema
- Examine chest for pleural effusion
- Examine abdomen for hepatomegaly and ascites
- Check bloods
- Review results
- Check ECG
- Hypokalaemia
- Hyperkalaemia
- U wave
- ST depression
- Peaked T wave

Check for signs of hyperlipidaemia

- Check skin and tendons for xanthomas
- Check eyes for arcus and xanthelasma
Biochemical investigations

There are three broad reasons why a clinician may request a biochemical laboratory investigation:

- to screen an asymptomatic subject for the presence of disease
- to assist in diagnosis of a patient’s presenting complaint
- to monitor changes in test results, as a marker of disease progression or response to treatment.

Contemporary medical practice has become increasingly reliant on laboratory investigation and, in particular, on biochemical investigation. This has been associated with extraordinary improvements in the analytical capacity and speed of laboratory instrumentation and the following operational trends:

- Large central biochemistry laboratories feature extensive use of automation and information technology. Specimens are transported from clinical areas to the laboratory using high-speed transport systems (such as pneumatic tubes) and identified with machine-readable labels (such as bar codes). Laboratory instruments have been miniaturised and integrated with robot transport systems to enable multiple rapid analyses of a single sample. Statistical process control techniques are used to assure the quality of analytical results, and increasingly to monitor other aspects of the laboratory, such as the time taken to complete the analysis (‘turn-around time’).
- Point-of-care testing (POCT) brings selected laboratory analytical systems into clinical areas, to the patient’s bedside or even connected to an individual patient. These systems allow the clinician to receive results almost instantaneously for immediate treatment of the patient, although often with lesser precision or at greater cost than using a central laboratory.
- The diversity of analyses has widened considerably with the introduction of many techniques borrowed from the chemical or other industries (Box 14.1).

Good medical practice involves the appropriate ordering of laboratory investigations and correct interpretation of test results (Box 14.2). The key principles, including the concepts of sensitivity and specificity, are described on page 4. Reference intervals for laboratory results are provided in Chapter 35. Many laboratory investigations can be subject to variability arising from whether the sample is being taken in the fed or fasted state; the timing of sample collection, in relation to diurnal variation of analytes; dosage intervals for therapeutic drug monitoring; sample type, such as serum, plasma; use of anticoagulants, such as EDTA, which can interfere with some assays; or artefacts, such as
in the extracellular fluid (ECF) compartment (Fig. 14.1). Most of the cells (the intracellular fluid or ICF), while the remaining 15 L is therefore about 40 L. Approximately 25 L is located inside for infants and less for women. In a 70 kg man TBW is in an adult male, although the proportion is somewhat more Total body water (TBW) is approximately 60% of body weight

in an appropriate container and with appropriate labelling. taking a venous sample proximal to the site of an intravenous infusion. It is therefore important for clinical and laboratory staff to communicate effectively and for clinicians to follow local recommendations concerning collection and transport of samples in the appropriate container and with appropriate labelling.

Water and electrolyte homeostasis

Total body water (TBW) is approximately 60% of body weight in an adult male, although the proportion is somewhat more for infants and less for women. In a 70 kg man TBW is therefore about 40 L. Approximately 25 L is located inside cells (the intracellular fluid or ICF), while the remaining 15 L is in the extracellular fluid (ECF) compartment (Fig. 14.1). Most of the ECF (approximately 12 L) is interstitial fluid, which is within the tissues but outside cells, whereas the remainder (about 3 L) is in the plasma compartment.

The ion composition between the main body fluid compartments intracellularly and extracellularly is illustrated in Figure 14.1. The dominant positively charged ion (cation) within cells is potassium, whereas phosphates and negatively charged proteins constitute the major intracellular negatively charged ions (anions). In the ECF the dominant cation is sodium, while chloride and, to a lesser extent, bicarbonate are the most important ECF anions. An important difference between the intravascular (plasma) and interstitial compartments of the ECF is that only plasma contains significant concentrations of protein.

The major force maintaining the difference in cation concentrations between the ICF and ECF is the sodium–potassium pump (Na,K-activated adenosine triphosphatase (ATPase)), which is present in all cell membranes. Maintenance of these gradients is essential for many cell processes, including the excitability of conducting tissues such as nerve and muscle. The difference in protein content between the plasma and the interstitial fluid compartment is maintained by the impermeability of the capillary wall to protein. This protein concentration gradient (the colloid osmotic, or oncotic, pressure of the plasma) contributes to the balance of forces across the capillary wall that favour fluid retention within the plasma compartment.

The concentration of sodium in the ECF plays a pivotal role in determining plasma osmolality and thereby controlling intracellular volume through changes in water balance between the intracellular and extracellular space. In contrast, plasma volume is largely controlled by total body sodium, which determines volume change. Therefore, disturbances in water homeostasis typically present with biochemical abnormalities such as hyponatraemia or hyponatraemia, whereas disturbances in sodium homeostasis present with hypervolaemia or hypovolaemia as the result of expansion or contraction of ECF volume, respectively.

Sodium homeostasis

Most of the body’s sodium is located in the ECF, where it is by far the most abundant cation. Accordingly, total body sodium is the principal determinant of ECF volume. Sodium intake varies widely between individuals, ranging between 50 and 250 mmol/24 hrs. The kidneys can compensate for these wide variations in sodium intake by increasing excretion of sodium when there is sodium overload, and retaining sodium in the presence of sodium depletion, to maintain normal ECF volume and plasma volume.

Functional anatomy and physiology

The functional unit for renal excretion is the nephron (Fig. 14.2). Blood undergoes ultrafiltration in the glomerulus, generating a
fluid that is free from cells and protein and which resembles plasma in its electrolyte composition. This is delivered into the renal tubules, where reabsorption of water and various electrolytes occurs. (More detail on the structure and function of the glomerulus is given in Ch. 15.) The glomerular filtration rate (GFR) is approximately 125 mL/min (equivalent to 180 L/24 hrs) in a normal adult. Over 99% of the filtered fluid is reabsorbed into the blood in the peritubular capillaries during its passage through successive segments of the nephron, largely as a result of tubular reabsorption of sodium. The processes mediating sodium reabsorption, and the factors that regulate it, are key to understanding clinical disturbances and pharmacological interventions of sodium and fluid balance.

The nephron can be divided into at least four different functional segments in terms of sodium reabsorption (Fig. 14.2).

Proximal renal tubule

About 65% of the filtered sodium load is reabsorbed in the proximal renal tubule. The cellular mechanisms are complex but some of the key features are shown in Figure 14.3A. Filtered sodium in the luminal fluid enters the proximal tubular cell through transporters in the apical membrane that couple sodium transport with sugars. Entry of sodium into the tubular cells at this site is mediated by the sodium–hydrogen exchanger (NHE-3). Intracellular H⁺ ions are generated within tubular cells from the breakdown of carbonic acid, which is produced from carbon dioxide and water under the influence of carbonic anhydrase. Large numbers of Na,K-ATPase pumps are present on the basolateral membrane of tubular cells, which transport sodium from the cells into the blood. In addition, a large component of the transepithelial flux of sodium, water and other dissolved solutes occurs through gaps between the cells (the ‘shunt’ pathway). Overall, fluid and electrolyte reabsorption is almost isotonic in this segment, as water reabsorption is matched very closely to sodium fluxes, such that the osmolality of fluid passing into the loop of Henle is very similar to that of plasma. A component of this water flow also passes through the cells, via aquaporin-1 (AQP-1) water channels, which are not sensitive to hormonal regulation.

Loop of Henle

The thick ascending limb of the loop of Henle (Fig. 14.3B) reabsorbs a further 25% of the filtered sodium but is impermeable to water, resulting in dilution of the luminal fluid. The primary driving force is the Na,K-ATPase on the basolateral cell membrane, but in this segment sodium enters the cell from the lumen through a specific carrier molecule, the Na,K,2Cl co-transporter (triple co-transporter, or NKCC2), which allows electroneutral entry of these ions into the renal tubular cell by balancing transport of anions (Na⁺/K⁺) with cations (Cl⁻). Some of the potassium accumulated inside the cell recirculates across the apical membrane back into the lumen through a specific potassium channel (ROMK), providing a continuing supply of potassium to match the high concentrations of sodium and chloride in the lumen. A small positive transepithelial potential difference exists in the lumen of this segment relative to the interstitium, and this serves to drive cations such as sodium, potassium, calcium and magnesium between the cells, forming a reabsorptive shunt pathway.

Early distal renal tubule

About 6% of filtered sodium is reabsorbed in the early distal tubule (also called distal convoluted tubule) (Fig. 14.3C), again driven by the activity of the basolateral Na,K-ATPase. In this segment, entry of sodium into the cell from the luminal fluid occurs through a sodium–chloride co-transport carrier (NCCT). This segment is also impermeable to water, resulting in further dilution of the luminal fluid. There is no significant transepithelial flux of potassium in this segment, but calcium is reabsorbed through the mechanism shown in Figure 14.3C: a basolateral sodium–calcium exchanger leads to low intracellular concentrations of calcium, promoting calcium entry from the luminal fluid through a calcium channel.

Late distal renal tubule and collecting ducts

The late distal tubule and cortical collecting duct are anatomically and functionally continuous (Fig. 14.3D). Here, sodium entry from the luminal fluid occurs through the epithelial sodium channel (ENaC), generating a substantial lumen-negative transepithelial potential difference. This sodium flux into the tubular cells is balanced by secretion of potassium and hydrogen ions into the lumen and by reabsorption of chloride ions. Potassium is accumulated in the cell by the basolateral Na,K-ATPase, and passes into the luminal fluid down its electrochemical gradient, through an apical potassium channel (ROMK). Chloride ions pass largely between cells. Hydrogen ion secretion is mediated by an H⁺-ATPase located on the luminal membrane of the intercalated cells, which constitute approximately one-third of the epithelial cells in this segment of the nephron. The distal tubule and collecting duct have a variable permeability to water, depending on circulating levels of vasopressin (antidiuretic hormone, ADH).

Fig. 14.2 The nephron. Letters A–D refer to tubular segments shown in more detail in Figure 14.3. (aa = afferent arteriole; ea = efferent arteriole; md = macula densa)
Sodium homeostasis

• Reduced perfusion pressure in the afferent arteriole
• Increased sympathetic nerve activity
• Decreased sodium chloride concentration in the distal tubular fluid.

Renin acts on the peptide substrate, angiotensinogen (which is produced by the liver), to produce angiotensin I, which is cleaved by angiotensin-converting enzyme (ACE), largely in the pulmonary capillary bed, to produce angiotensin II (see Fig. 18.18, p. 666). Angiotensin II has multiple actions: it stimulates proximal tubular sodium reabsorption and release of aldosterone from the zona glomerulosa of the adrenal cortex, and causes vasoconstriction of small arterioles. Aldosterone amplifies sodium reabsorption in this segment to a maximum of 2–3% of the filtered sodium load.

Less than 1% of sodium reabsorption occurs in the medullary collecting duct, where it is inhibited by atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP).

**Regulation of sodium transport**

The amount of sodium excreted by the kidney is dependent on the filtered load of sodium (which is largely determined by GFR) and the control of tubular sodium reabsorption. A number of interrelated mechanisms serve to maintain whole-body sodium balance, and hence ECF volume, by matching urinary sodium excretion to sodium intake (Fig. 14.4), and controlling those two processes.

Important sensing mechanisms include volume receptors in the cardiac atria and the intrathoracic veins, as well as pressure receptors located in the central arterial tree (aortic arch and carotid sinus) and the afferent arterioles within the kidney. A further afferent signal is generated within the kidney itself: the enzyme renin is released from specialised smooth muscle cells in the walls of the afferent and efferent arterioles, at the point where they make contact with the early distal tubule (at the macula densa; see Fig. 14.2) to form the juxtaglomerular apparatus. Renin release is stimulated by:

- reduced perfusion pressure in the afferent arteriole
- increased sympathetic nerve activity
- decreased sodium chloride concentration in the distal tubular fluid.

Renin acts on the peptide substrate, angiotensinogen (which is produced by the liver), to produce angiotensin I, which is cleaved by angiotensin-converting enzyme (ACE), largely in the pulmonary capillary bed, to produce angiotensin II (see Fig. 18.18, p. 666). Angiotensin II has multiple actions: it stimulates the SGLT2 inhibitors are primarily used for the treatment of diabetes but have diuretic properties by blocking SGLT2 in the proximal tubule. At the same site, acetazolamide inhibits carbonic anhydrase (CA), which, by reducing production of hydrogen ions by proximal tubular cells, inhibits sodium-hydrogen exchange through the NHE-3 transporter. Loop diuretics block the NKCC2 transporter in the loop of Henle, whereas thiazide diuretics block the NCCT channel in the early distal tubule. Amiloride and spironolactone block the ENaC channel in the late distal tubule and collecting ducts. See text for further details and abbreviations.

**Fig. 14.3 Principal transport mechanisms in segments of the nephron.** The apical membrane of tubular cells is the side facing the lumen and the basolateral membrane is the side facing the blood. Black circles indicate active transport pumps linked to ATP hydrolysis and white symbols indicate ion channels and transporter molecules. Details of the proportion of sodium reabsorbed, influence of regulatory factors, water permeability and sites of action for different classes of diuretics are shown. The SGLT2 inhibitors are primarily used for the treatment of diabetes but have diuretic properties by blocking SGLT2 in the proximal tubule. At the same site, acetazolamide inhibits carbonic anhydrase (CA), which, by reducing production of hydrogen ions by proximal tubular cells, inhibits sodium-hydrogen exchange through the NHE-3 transporter. Loop diuretics block the NKCC2 transporter in the loop of Henle, whereas thiazide diuretics block the NCCT channel in the early distal tubule. Amiloride and spironolactone block the ENaC channel in the late distal tubule and collecting ducts. See text for further details and abbreviations.
Hypovolaemia is defined as a reduction in circulating blood volume. The most common causes are loss or sequestration of sodium-containing fluids or acute blood loss, as summarised in Box 14.4.

**Pathogenesis**

Loss of sodium-containing fluid triggers the changes in renal sodium handling and activation of the renin–angiotensin system that were described on page 349. Loss of whole blood, as in acute haemorrhage, is another cause of hypovolaemia, and elicits the same mechanisms for the conservation of sodium and water as loss of sodium-containing fluid.

**Clinical features**

Hypovolaemia is primarily a clinical diagnosis, based on characteristic symptoms such as thirst, dizziness and weakness along with characteristic clinical signs (see Box 14.3) in the context of a relevant precipitating illness.

**Investigations**

Serum sodium concentrations are usually normal in hypovolaemia. The GFR is usually maintained unless the hypovolaemia is very severe or prolonged, but urinary flow rate is reduced as a consequence of activation of sodium- and water-retaining mechanisms in the nephron. Serum creatinine, which reflects GFR, is usually normal, but serum urea concentration is typically elevated due to a low urine flow rate, which is accompanied by its action on the cortical collecting duct. The net effect of activation of the renin–angiotensin system is to raise blood pressure and cause sodium and water retention, thereby correcting hypovolaemia.

Changes in GFR alter peritubular hydrostatic pressure and oncotic pressure in opposite directions, resulting in a change in sodium reabsorption. In particular, with hypovolaemia, and a reduction in hydrostatic pressure and an increase in oncotic pressure, there is an increase in sodium reabsorption.

The sympathetic nervous system also acts to increase sodium retention, both through haemodynamic mechanisms (afferent arteriolar vasoconstriction and GFR reduction) and by direct stimulation of proximal tubular sodium reabsorption. In contrast, other humoral mediators, such as the natriuretic peptides, which inhibit sodium reabsorption, contribute to natriuresis during periods of sodium and volume excess.

Increases in sodium intake cause hypervolaemia, which increases renal perfusion and GFR and suppresses renin production through increased delivery of sodium into the macula densa. This sets in motion a train of events opposite to those that occur in hypovolaemia, to cause an increase in sodium excretion.

**Presenting problems in sodium and water balance**

When the balance of sodium intake and excretion is disturbed, any tendency for plasma sodium concentration to change is usually corrected by the osmotic mechanisms controlling water balance (p. 349). As a result, disorders in sodium balance present chiefly as alterations in the ECF volume, resulting in hypovolaemia or hypervolaemia, rather than as an alteration in plasma sodium concentration. Clinical manifestations of altered ECF volume are illustrated in Box 14.3.

**Hypovolaemia**

Hypovolaemia is defined as a reduction in circulating blood volume. The most common causes are loss or sequestration...
by increased tubular reabsorption of urea. Similarly, serum uric acid may also rise, reflecting increased reabsorption in the proximal renal tubule. The urine osmolality increases due to increased reabsorption of sodium and water, while the urine sodium concentration falls and sodium excretion may fall to less than 0.1% of the filtered sodium load.

Management

Management of sodium and water depletion has two main components:

- treat the cause where possible, to stop ongoing salt and water losses
- replace the salt and water deficits, and provide ongoing maintenance requirements, usually by intravenous fluid replacement when depletion is severe.

Intravenous fluid therapy

Intravenous fluid therapy can be used to maintain water, sodium and potassium intake when the patient is fasting, such as during an acute illness or post-operatively. If any deficits or continuing pathological losses are identified, additional fluid and electrolytes will be required. In prolonged periods of fasting (more than a few days), attention also needs to be given to providing sufficient caloric and nutritional intake to prevent excessive catabolism of body energy stores (p. 704). The daily maintenance requirements for water and electrolytes in a typical adult are shown in Box 14.5 and the composition of some widely available intravenous fluids are given in Box 14.6. The choice of fluid and the rate of administration depend on the clinical circumstances, as assessed at the bedside and from laboratory data, as described in Box 14.7.

The choice of intravenous fluid therapy in the treatment of significant hypovolaemia relates to the concepts in Figure 14.1. If fluid containing neither sodium nor protein is given, it will distribute in the body fluid compartments in proportion to the normal distribution of total body water. For example, administration of 1 L of 5% dextrose contributes little (approximately 3/40 of the infused volume) towards expansion of the plasma volume, which makes this fluid unsuitable for restoring the circulation and perfusion of vital organs. Intravenous infusion of an isotonic (normal) saline solution, on the other hand, is more effective at correcting hypovolaemia than protein-free fluids (crystalloids). However, recent clinical studies have not shown any advantage of giving albumin-containing infusions in the treatment of acute hypovolaemia. Furthermore, synthetic colloids such as dextran have been shown to be associated with an increased risk of acute kidney injury and mortality in the critically ill. Therefore, crystalloids are the fluid of choice for resuscitation in acute hypovolaemia. More studies, however, are required to clarify the most appropriate crystalloid in this situation, given that normal saline can cause a mild metabolic acidosis, perhaps related to excessive chloride loading, whereas ‘balanced solutions’, such as Hartmann’s, may cause a mild hyponatraemia, as its composition is slightly hypotonic.

Hypervolaemia

Hypervolaemia is the result of sodium and water excess and is rare in patients with normal cardiac and renal function, since

the kidney has a large capacity to increase renal excretion of sodium and water via the homeostatic mechanisms described on page 349.

Pathogenesis

The most common systemic disorders responsible for hypervolaemia are outlined in Box 14.8. In cardiac failure, cirrhosis and nephrotic syndrome, sodium retention occurs in response to circulatory insufficiency caused by the primary disorder, as illustrated in Figure 14.5. The pathophysiology is different in renal failure, when the primary cause of volume expansion is the profound reduction in GFR impairing sodium and water excretion, while secondary tubular mechanisms are of lesser importance. In Conn’s syndrome (p. 674), the pathophysiology also differs, in that increased secretion of aldosterone directly stimulates sodium reabsorption.

Clinical features

Peripheral oedema is the most common physical sign of hypervolaemia since the excess fluid leaks out of the capillaries to expand the interstitial compartment of the ECF. This is particularly the case in nephrotic syndrome and chronic liver disease, in which hypoalbuminaemia is a prominent feature. The main exception is primary hyperaldosteronism (Conn’s syndrome), which presents with hypertension and often hypokalaemia, but in which peripheral oedema is not commonly seen.

Investigations

Although hypervolaemia is accompanied by an excess of total body sodium, serum sodium concentrations are normal due to the accompanying water retention. Serum concentrations of potassium are normal except in Conn’s syndrome, where there is hypokalaemia due to the increased aldosterone production (p. 674). Creatinine, GFR and urea are usually normal, unless the underlying cause of hypervolaemia is renal failure. General investigations may reveal evidence of cardiac, renal or liver disease.

Management

The management of hypervolaemia involves a number of components:

- specific treatment directed at the underlying cause, such as ACE inhibitors in heart failure and glucocorticoids in minimal change nephropathy
- restriction of dietary sodium (to 50–80 mmol/24 hrs) to match the diminished excretory capacity
- treatment with diuretics.

Diuretic therapy

Diuretics play a pivotal role in the treatment of hypervolaemia due to salt and water retention and in hypertension (p. 513). They act by inhibiting sodium reabsorption at various locations along the nephron (see Fig. 14.3). Their potency and adverse effects relate to their mechanism and site of action.

Carbonic anhydrase inhibitors

Acetazolamide is a carbonic anhydrase inhibitor that inhibits intracellular production of H⁺ ions in the proximal tubule, reducing the fraction of sodium reabsorption that is exchanged for H⁺ by the apical membrane sodium–hydrogen exchanger. It is a weak diuretic but is seldom used clinically for this purpose, since only a small fraction of proximal sodium reabsorption uses this mechanism, and much of the sodium that is not reabsorbed in the proximal tubule can be reabsorbed by downstream segments of the nephron.

Sodium-dependent glucose transporter inhibitors

Inhibitors of the sodium-dependent glucose transporter 2 (SGLT2), such as dapagliflozin and canagliflozin, simultaneously block glucose and sodium reabsorption in the proximal tubule. They have mild diuretic properties but are principally used to lower blood glucose in the treatment of diabetes (p. 745).

Loop diuretics

Loop diuretics, such as furosemide, inhibit sodium reabsorption in the thick ascending limb of the loop of Henle, by blocking the action of the apical membrane NKCC2 co-transporter. Because this segment reabsorbs a large fraction of
of the filtered sodium, these drugs are potent diuretics, and are commonly used in diseases associated with significant oedema. Loop diuretics cause excretion not only of sodium (and with it water) but also of potassium. This occurs largely as a result of delivery of increased amounts of sodium to the late distal tubule and cortical collecting ducts, where sodium reabsorption is associated with excretion of potassium, and is amplified if circulating aldosterone levels are high.

**Thiazide diuretics** Thiazide diuretics inhibit sodium reabsorption in the early distal tubule, by blocking the NCCT co-transporter in the apical membrane. Since this segment reabsorbs a much smaller fraction of the filtered sodium, these are less potent than loop diuretics, but are widely used in the treatment of hypertension and less severe oedema. Like loop diuretics, thiazides increase excretion of potassium through delivery of increased amounts of sodium to the late distal tubule and collecting duct. They are the diuretics that are most likely to be complicated by the development of hypokalaemia, as outlined on page 357.

**Potassium-sparing diuretics** Potassium-sparing diuretics act on the late distal renal tubule and cortical collecting duct segment to inhibit sodium reabsorption. Since sodium reabsorption and potassium secretion are linked at this site, the reduced sodium reabsorption is accompanied by reduced potassium secretion. The apical sodium channel (see Fig. 14.3) is blocked by amiloride and triamterene, while spironolactone and eplerenone also act at this site by blocking binding of aldosterone to the mineralocorticoid receptor.

**Osmotic diuretics** These act independently of a specific transport mechanism. As they are freely filtered at the glomerulus but not reabsorbed by any part of the tubular system, they retain fluid osmotically within the tubular lumen and limit the extent of sodium reabsorption in multiple segments. Mannitol is the most commonly used osmotic diuretic. It is given by intravenous infusion to achieve short-term diuresis in conditions such as cerebral oedema.

**Clinical use of diuretics**

The following principles should be observed when using diuretics:

- Use the minimum effective dose.
- Use for as short a period of time as necessary.
- Monitor regularly for adverse effects.

The choice of diuretic is determined by the potency required, the presence of coexistent conditions, and the side-effect profile. Adverse effects encountered with the most frequently used classes of diuretic (loop drugs and thiazide drugs) are summarised in Box 14.9. Volume depletion and electrolyte disorders are the most common, as predicted from their mechanism of action. The metabolic side-effects listed are rarely of clinical significance and may reflect effects on K⁺ channels that influence insulin secretion (p. 723). Since most drugs from these classes are sulphonamides, there is a relatively high incidence of hypersensitivity reactions, and occasional idiosyncratic side-effects in a variety of organ systems. The side-effect profile of the potassium-sparing diuretics differs in a number of important respects from that of other diuretics. The disturbances in potassium, magnesium and acid–base balance are in the opposite direction, so that normal or increased levels of potassium and magnesium are found in the blood, and there is a tendency to metabolic acidosis, especially when renal function is impaired.

An important feature of the most commonly used diuretic drugs (furosemide, thiazides and amiloride) is that they act on their target molecules from the luminal side of the tubular epithelium. Since they are highly protein-bound in the plasma, very little reaches the urinary fluid by glomerular filtration, but there are active transport mechanisms for secreting organic acids and bases, including these drugs, across the proximal tubular wall into the lumen, resulting in adequate drug concentrations being delivered to later tubular segments. This secretory process may be impaired by certain other drugs, and also by accumulated organic anions as occurs in chronic kidney disease and chronic liver failure, leading to resistance to diuretics.

Diuretic resistance is encountered under a variety of circumstances, including impaired renal function, activation of sodium-retaining mechanisms, impaired oral bioavailability (such as in patients with gastrointestinal disease) and decreased renal blood flow. In these circumstances, short-term intravenous therapy with a loop-acting agent such as furosemide may be useful. Combinations of diuretics administered orally may also increase potency. Either a loop or a thiazide drug can be combined with a potassium-sparing drug, and all three classes can be used together for short periods, with carefully supervised clinical and laboratory monitoring.

### Water homeostasis

Daily water intake can vary from about 500 mL to several litres a day. About 800 mL of water is lost daily through the stool, sweat and the respiratory tract (insensible losses) and about 400 mL is generated daily through oxidative metabolism (metabolic water). The kidneys are chiefly responsible for adjusting water excretion to balance intake, endogenous production and losses so as to maintain total body water content and serum osmolality within the reference range of 280–296 mOsmol/kg.

### Functional anatomy and physiology

While regulation of total ECF volume is largely achieved through renal control of sodium excretion, mechanisms exist to allow for the excretion of urine that is hypertonic or hypotonic in relation to plasma to maintain constant plasma osmolality.

These functions are largely achieved by the loop of Henle and the collecting ducts (see Fig. 14.2). The countercurrent configuration of flow in adjacent limbs of the loop (Fig. 14.6) involves osmotic movement of water from the descending limbs and reabsorption of
osmolality approaching that in the medullary tip (up to 1200 mOsmol/kg).

Parallel to these changes in vasopressin release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:
- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- absence of vasopressin in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:
- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- vasopressin release into the circulation
- vasopressin action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Solute from neighbouring ascending limbs, to set up a gradient of osmolality from isotonic (like plasma) in the renal cortex to hypertonic (around 1200 mOsmol/kg) in the inner part of the medulla. At the same time, the fluid emerging from the thick ascending limb is hypotonic compared to plasma because it has been diluted by the reabsorption of sodium, but not water, from the thick ascending limb and is further diluted in the early distal tubule. As this dilute fluid passes from the cortex through the collecting duct system to the renal pelvis, it traverses the medullary interstitial gradient of osmolality set up by the operation of the loop of Henle, and water is able to be reabsorbed.

Further changes in the urine osmolality on passage through the collecting ducts depend on the circulating level of vasopressin, which is released by the posterior pituitary gland under conditions of increased plasma osmolality or hypovolaemia (p. 688).

- When water intake is high and plasma osmolality is normal or low-normal (Fig. 14.6B), vasopressin levels are suppressed and the collecting ducts remain impermeable to water. The luminal fluid osmolality remains low, resulting in the excretion of a dilute urine (minimum osmolality approximately 50 mOsmol/kg in a healthy young person).
- When water intake is restricted and plasma osmolality is high (Fig. 14.6A), or in the presence of plasma volume depletion, vasopressin levels rise. This causes water permeability of the collecting ducts to increase through binding of vasopressin to the V2 receptor, which enhances collecting duct water permeability through the insertion of AQP-2 channels into the luminal cell membrane. This results in osmotic reabsorption of water along the entire length of the collecting duct, with maximum urine osmolality approaching that in the medullary tip (up to 1200 mOsmol/kg).

Parallel to these changes in vasopressin release are changes in water-seeking behaviour triggered by the sensation of thirst, which also becomes activated as plasma osmolality rises.

In summary, for adequate dilution of the urine there must be:
- adequate solute delivery to the loop of Henle and early distal tubule
- normal function of the loop of Henle and early distal tubule
- absence of vasopressin in the circulation.

If any of these processes is faulty, water retention and hyponatraemia may result.

Conversely, to achieve concentration of the urine there must be:
- adequate solute delivery to the loop of Henle
- normal function of the loop of Henle
- vasopressin release into the circulation
- vasopressin action on the collecting ducts.

Failure of any of these steps may result in inappropriate water loss and hypernatraemia.

Presenting problems in regulation of osmolality

Changes in plasma osmolality are largely determined by changes in serum sodium concentration and its associated anions. Changes in sodium concentration usually occur because of disturbances in water balance either because there is a relative excess of body water compared to total body sodium (hyponatraemia) or
a relative lack of body water compared to total body sodium (hypermotraemia). Abnormalities of water balance can result from disturbances in urinary concentration or dilution.

If extracellular osmolality falls abruptly, water flows rapidly across cell membranes, causing cell swelling, whereas cell shrinkage occurs when osmolality rises. Cerebral function is particularly sensitive to such volume changes, particularly brain swelling during hypo-osmolality, which can lead to an increase in intracerebral pressure and reduced cerebral perfusion.

Hyponatraemia

Hyponatraemia is defined as a serum Na < 135 mmol/L. It is a common electrolyte abnormality with many potential underlying causes, as summarised in Box 14.10.

Pathophysiology

In all cases, hyponatraemia is caused by greater retention of water relative to sodium. The causes are best categorised according to associated changes in body water content and the patient is clinically euvolaemic. Excess body water may be the result of abnormally high intake, either orally (primary polydipsia) or as a result of medically infused fluids (as intravenous dextrose solutions, or by absorption of sodium-free bladder irrigation fluid after prostatectomy).

Water retention also occurs in the syndrome of inappropriate secretion of antidiuretic hormone, or vasopressin (SIADH). In this condition, an endogenous source of vasopressin (either cerebral or tumour-derived) promotes water retention by the kidney in the absence of an appropriate physiological stimulus (Box 14.11). The clinical diagnosis requires the patient to be euvoalaemic, with no evidence of cardiac, renal or hepatic disease potentially associated with hyponatraemia. Other non-osmotic stimuli that cause release of vasopressin (pain, stress, nausea) should also be excluded. Supportive laboratory findings are shown in Box 14.11.

Hyponatraemia with hypovolaemia

In this situation, excess water retention is associated with sodium retention and volume expansion, as in heart failure, liver disease or kidney disease.

Clinical features

Hyponatraemia is often asymptomatic but can also be associated with profound disturbances of cerebral function, manifesting as anorexia, nausea, vomiting, delirium, lethargy, seizures and coma. The likelihood of symptoms occurring is related to the speed at which hyponatraemia develops rather than the severity of hyponatraemia. This is because water rapidly flows into cerebral cells when plasma osmolality falls acutely, causing them to become swollen and ischaemic. However, when hyponatraemia develops gradually, cerebral neurons have time to respond by reducing intracellular osmolality, through excreting potassium and reducing synthesis of intracellular organic osmolytes (Fig. 14.7). The osmotic gradient favouring water movement into the cells is thus reduced and symptoms are avoided. This process takes about 24–48 hours and hyponatraemia is therefore classified as acute (<48 hours) and chronic (>48 hours). Hyponatraemia can also be defined as mild (130–135 mmol/L), moderate (125–129 mmol/L) or severe (<124 mmol/L), based on biochemical findings or on the degree of severity of symptoms (Box 14.12).

Investigations

An algorithm for the clinical assessment of patients with hyponatraemia is shown in Figure 14.8. Artefactual causes of hyponatraemia should be considered in all cases. These include severe hyperlipidaemia or hyperproteininaemia, when the aqueous fraction of the serum specimen is reduced because of the volume occupied by the macromolecules (although this artefact is dependent on the assay technology). Transient hyponatraemia

(SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion; see Box 14.11.)

### 14.11 Causes and diagnosis of syndrome of inappropriate antidiuretic hormone secretion

#### Causes
- Tumours
- Central nervous system disorders: stroke, trauma, infection, psychosis, porphyria
- Pulmonary disorders: pneumonia, tuberculosis, obstructive lung disease
- Drugs: anticonvulsants, psychotropics, antidepressants, cytotoxics, oral hypoglycaemic agents, opiates
- Idiopathic

#### Diagnosis
- Low plasma sodium concentration (typically < 130 mmol/L)
- Low plasma osmolality (< 275 mOsmol/kg)
- Urine osmolality not minimally low (typically > 100 mOsmol/kg)
- Urine sodium concentration not minimally low (>30 mmol/L)
- Low–normal plasma urea, creatinine, uric acid
- Clinical euvoalaemia
- Absence of adrenal, thyroid, pituitary or renal insufficiency
- No recent use of diuretics
- Exclusion of other causes of hyponatraemia (see Box 14.10)
- Appropriate clinical context (above)
urine electrolytes and osmolality (Fig. 14.8) are usually the only tests required to clarify the underlying cause. Hypovolaemic hyponatraemia is characterised by a low urinary sodium concentration (<30 mmol/L) when there are extrarenal causes of sodium loss and high urinary sodium concentration (>30 mmol/L) in patients with excessive renal sodium loss.

Measurement of vasopressin is not generally helpful in distinguishing between different categories of hyponatraemia. This is because concentrations of vasopressin are raised both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates vasopressin release through non-osmotic mechanisms. Indeed, patients with these disorders may have higher circulating vasopressin (ADH) levels than patients with SIADH. The only disorders listed in Box 14.10 in which vasopressin is suppressed are primary polydipsia and iatrogenic water intoxication, where the hypo-osmolar state inhibits vasopressin release from the pituitary.

**Management**

The treatment of hyponatraemia is critically dependent on its rate of development, severity, presence of symptoms and underlying cause. If hyponatraemia has developed rapidly (<48 hours) and there are signs of cerebral oedema, such as obtundation or convulsions, sodium levels should be restored rapidly to normal by infusion of hypertonic (3%) sodium chloride. A common approach is to give an initial bolus of 150 mL over 20 minutes, which may be repeated once or twice over the initial hours of observation, depending on the neurological response and rise in plasma sodium.

Rapid correction of hyponatraemia that has developed more slowly (>48 hours) can be hazardous, since brain cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 14.7). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of neurons, abruptly reducing their volume and causing them to detach from their myelin sheaths. The resulting ‘myelinolysis’ can produce permanent structural and functional damage to mid-brain structures, and is generally fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/24 hrs, and an even slower rate is generally safer.

The underlying cause should also be treated. For hypovolaemic patients, this involves controlling the source of sodium loss, and administering intravenous saline if clinically warranted. Patients with euvolaemic hyponatraemia generally respond to fluid restriction in the range of 600–1000 mL/24 hrs, accompanied where possible by withdrawal of the precipitating stimulus (such as drugs causing SIADH). In patients with persistent hyponatraemia due to prolonged SIADH, oral urea therapy (30–45 g/day) can be used, which provides a solute load to promote water excretion. Oral vasopressin receptor antagonists such as tolvaptan may also be used to block the vasopressin-mediated component of water retention in a range of hyponatraemic conditions, but concerns exist with regard to the risk of overly rapid correction of hyponatraemia with these agents. Hypervolaemic patients with hyponatraemia need treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context when there is significant secondary hyperaldosteronism.

**Hypernatraemia**

Hypernatraemia is defined as existing when the serum Na is >145 mmol/L. The causes are summarised in Box 14.13, grouped according to any associated disturbance in total body sodium content.

**Pathophysiology**

Hypernatraemia occurs due to inadequate concentration of the urine in the face of restricted water intake. This can arise because...
Water homeostasis

• Of failure to generate an adequate medullary concentration gradient in the kidney due to low GFR or loop diuretic therapy, but more commonly is caused by failure of the vasopressin system. This can occur because of pituitary damage (cranial diabetes insipidus, p. 687) or because the collecting duct cells are unable to respond to circulating vasopressin concentrations in the face of restricted water intake (nephrogenic diabetes insipidus). Whatever the underlying cause, sustained or severe hypernatraemia generally reflects an impaired thirst mechanism or responsiveness to thirst.

Clinical features

Patients with hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water,
hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, delirium, weakness and, ultimately, coma and death can result.

Management
Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly, neuronal shrinkage may be acute and relatively rapid correction may be attempted. This can be achieved by infusing an appropriate volume of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) at an initial rate of 50–70 mL/hr. In older, institutionalised patients, however, it is more likely that the disease has developed slowly, and extreme caution should be exercised in lowering plasma sodium to avoid the risk of cerebral oedema. Where possible, the underlying cause should also be addressed (Box 14.13).

Elderly patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in elderly patients with recent alterations in behaviour (Box 14.14).

Potassium homeostasis
Potassium is the major intracellular cation (see Fig. 14.1), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential that is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

Functional anatomy and physiology
The kidneys normally excrete some 90% of the daily intake of potassium, typically 80–100 mmol/24 hrs. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. Little potassium is transported in the early distal tubule but a significant secretory flux of potassium into the urine occurs in the late distal tubule and cortical collecting duct to ensure that the amount removed from the blood is proportional to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in Figure 14.3D. Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through the ROMK channel into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

A number of factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal tubule and cortical collecting ducts. This is a major factor responsible for the increased potassium loss that accompanies diuretic treatment. Agents interfering with the generation of the negative luminal potential also impair potassium secretion, and this is the basis of reduced potassium secretion associated with potassium-sparing diuretics such as amiloride. Factors acting on the blood side of this tubular segment include plasma potassium and pH, such that hyperkalaemia and alkalosis both enhance potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is aldosterone.

As shown in Figure 14.9, a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the renin–angiotensin system (see Fig. 18.18, p. 666), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium. Aldosterone then acts on the kidney to enhance potassium secretion, hydrogen secretion and sodium reabsorption, in the late distal tubule and cortical collecting ducts. The resulting increased excretion of potassium maintains plasma potassium within a narrow range (3.6–5.0 mmol/L). Factors that reduce angiotensin II levels may indirectly affect potassium balance by blunting the rise in aldosterone that would otherwise be provoked by hyperkalaemia. This accounts for the increased risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.
Potassium homeostasis

Presenting problems in potassium homeostasis

Changes in the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells by extracellular alkalosis and by a number of hormones, including insulin, catecholamines (through the β₂-receptor) and aldosterone. Any of these factors can produce hypokalaemia, whereas extracellular acidosis, lack of insulin, and insufficiency or blockade of catecholamines or aldosterone can cause hyperkalaemia due to efflux of potassium from the intracellular compartment.

Hypokalaemia

Hypokalaemia is a common electrolyte disturbance and is defined as existing when serum K⁺ falls below 3.5 mmol/L. The main causes of hypokalaemia are shown in Box 14.15.

Pathophysiology

Hypokalaemia is generally indicative of abnormal potassium loss from the body, through either the kidney or the gastrointestinal tract. Renal causes of hypokalaemia can be divided into those with and those without hypertension. Hypokalaemia in the presence of hypertension may be due to increased aldosterone secretion in Conn’s syndrome (p. 674) or a genetic defect affecting sodium channels in the distal nephron (Liddle’s syndrome). Excessive intake of liquorice or treatment with carbonoxolone may result in a similar clinical picture, due to inhibition of the renal 11βHSD2 enzyme, which inactivates cortisol in peripheral tissues.

If blood pressure is normal or low, hypokalaemia can be classified according to the associated change in acid–base balance. Inherited defects in tubular transport should be suspected when hypokalaemia occurs in association with alkalosis, provided that diuretic use has been excluded. One such disease is Bartter’s syndrome, in which sodium reabsorption in the thick ascending limb of Henle is defective, usually due to a loss-of-function mutation of the NKCC2 transporter. The clinical and biochemical features are similar to those in chronic treatment with furosemide. In Gitelman’s syndrome there is a loss-of-function mutation affecting the NCCT transporter in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter’s and Gitelman’s syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter’s syndrome but decreased in Gitelman’s syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see Box 14.9).

If hypokalaemia occurs in the presence of a normal blood pressure and metabolic acidosis, renal tubular acidosis (proximal or ‘classical’ distal) should be suspected (p. 364).

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting, the hypokalaemia is characteristically associated with metabolic alkalosis, due to loss of gastric acid. If, however, potassium loss has occurred through the surreptitious use of aperients, the hypokalaemia is generally associated with metabolic acidosis. In both cases, urinary potassium excretion is low unless there is significant extracellular volume depletion, which can raise urinary potassium levels by stimulating aldosterone production.

Hypokalaemia can also be caused by redistribution of potassium into cells as the result of insulin, β-adrenoceptor agonists and alkalosis, or as the result of K⁺ influx into muscle in hypokalaemic periodic paralysis, which is associated with mutations in several genes that regulate transmembrane ion flow into muscle cells. Finally, reduced dietary intake of potassium can contribute to hypokalaemia but is seldom the only cause, except in extreme cases.

Clinical features

Patients with mild hypokalaemia (plasma K⁺ 3.0–3.3 mmol/L) are generally asymptomatic, but more profound reductions in plasma potassium often lead to muscular weakness and associated tiredness. Ventricular ectopic beats or more serious arrhythmias may occur and the arrhythmogenic effects of digoxin may be potentiated. Typical electrocardiogram (ECG) changes occur, affecting the T wave in particular (p. 347). Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia may cause renal tubular damage (hypokalaemic nephropathy) and can interfere with the tubular response to vasopressin (acquired nephrogenic diabetes insipidus), resulting in polyuria and polydipsia.
**Investigations**

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. If the diagnosis remains unclear, plasma renin should be measured. Levels are low in patients with primary hyperaldosteronism (p. 674) and other forms of mineralocorticoid excess, but raised in other causes of hypokalaemia. When there is no obvious clinical clue to which pathway is involved, measurement of urinary potassium may be helpful; if the kidney is the route of potassium loss, the urine potassium is high (>30 mmol/24 hrs), whereas if potassium is being lost through the gastrointestinal tract, the kidney retains potassium, resulting in a lower urinary potassium (generally <20 mmol/24 hrs). It should be noted, however, that if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

The cause of hypokalaemia may remain unclear despite the above investigations when urinary potassium measurements are inconclusive and the history is incomplete or unreliable. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride (<30 mmol/L) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride >40 mmol/L suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter’s or Gitelman’s syndrome. Differentiation between occult diuretic therapy (acute phase) or a tubular disorder such as hypokalaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

**Management**

Treatment of hypokalaemia involves first determining the cause and correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of the process responsible may be sufficient to restore plasma potassium without providing supplements. In most cases, however, some form of potassium replacement will be required. This can generally be achieved with slow-release potassium chloride tablets, but in more acute circumstances intravenous potassium chloride may be necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular complications, but should generally not exceed 10 mmol of potassium per hour. In patients with severe, life-threatening hypokalaemia, the concentration of potassium in the infused fluid may be increased to 40 mmol/L if a peripheral vein is used, but higher concentrations must be infused into a large ‘central’ vein with continuous cardiac monitoring.

In the less common situation where hypokalaemia occurs in the presence of systemic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may also be required, since low cell magnesium can promote tubular potassium secretion, causing ongoing urinary losses. In some circumstances, potassium-sparing diuretics, such as amiloride, can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when renal loss of potassium is the underlying cause.

**Hyperkalaemia**

Hyperkalaemia is a common electrolyte disorder, which is defined as existing when serum K+ is >5 mmol/L. The causes of hyperkalaemia are summarised in Box 14.16.

### Pathophysiology

It is important to remember that hyperkalaemia can be artefactual due to haemolysis of blood specimens during collection or in vitro, or due to release of potassium from platelets in patients with thrombocytosis.

True hyperkalaemia, however, can occur either because of redistribution of potassium between the ICF and ECF, or because potassium intake exceeds excretion. Redistribution...
of potassium from the ICF to the ECF may take place in the presence of systemic acidosis, or when the circulating levels of insulin, catecholamines and aldosterone are reduced, or when the effects of these hormones are blocked (p. 361).

High dietary potassium intake may contribute to hyperkalaemia, but is seldom the only explanation unless renal excretion mechanisms are impaired. The mechanism of hyperkalaemia in acute kidney injury and chronic kidney disease is impaired excretion of potassium into the urine as the result of a reduced GFR. In addition, acute kidney injury can be associated with severe hyperkalaemia when there is an increased potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is present. In chronic kidney disease, adaptation to moderately elevated plasma potassium levels commonly occurs. However, acute rises in potassium triggered by excessive dietary intake, hypovolaemia or drugs (see below) may occur and destabilise the situation.

Hyperkalaemia can also develop when tubular potassium secretory processes are impaired, even if the GFR is normal. This can arise in association with low levels of aldosterone, as is found in Addison’s disease, hyperreninaemic hypoaldosteronism, or inherited disorders such as congenital isolated hypoaldosteronism, in which there is a defect in aldosterone biosynthesis, and pseudohypoaldosteronism type 2 (Gordon’s syndrome), caused by mutations in the WNK2 and WNK4 genes, which causes decreased potassium secretion in the renal tubules.

Drug-induced causes include ACE inhibitors, angiotensin-receptor blockers (ARBs), non-steroidal anti-inflammatory drugs (NSAIDs) and β-adrenoceptor antagonists (β-blockers).

In another group of conditions, tubular potassium secretion is impaired as the result of aldosterone resistance. This can occur in a variety of diseases in which there is inflammation of the tubulointerstitium, such as systemic lupus erythematosus; following renal transplantation; during treatment with potassium-sparing diuretics; and in a number of inherited disorders of tubular transport.

In aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal (‘type 4’) renal tubular acidosis (p. 364).

Clinical features
Mild to moderate hyperkalaemia (<6.5 mmol/L) is usually asymptomatic. More severe hyperkalaemia can present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest occurs. The typical ECG changes are shown on page 347. Peaking of the T wave is an early ECG sign, but widening of the QRS complex presages a dangerous cardiac arrhythmia. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective. In renal failure, dialysis may be required. Oral ion exchange resins, such as sodium polystyrene sulfonate (SPS), have traditionally been used to bind and excrete gastrointestinal potassium. There are concerns, however, with regard to SPS’s lack of proven efficacy and safety, with a number of reports of intestinal necrosis associated with its use. Alternative cation exchanges have been developed and are currently being trialled, with the aim of providing more effective and safer alternatives for the treatment of hyperkalaemia.

Management
Treatment of hyperkalaemia depends on its severity and the rate of development, but opinions vary as to what level of serum potassium constitutes severe hyperkalaemia and requires urgent treatment. Patients who have potassium concentrations <6.5 mmol/L in the absence of neuromuscular symptoms or ECG changes can be treated with a reduction of potassium intake and correction of predisposing factors. However, in acute and/or severe hyperkalaemia (plasma potassium >6.5–7.0 mmol/L), more urgent measures must be taken (Box 14.17). The first step should be infusion of 10 mL 10% calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be applied, as they generally have a rapid effect and may avert arrhythmias. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective. In renal failure, dialysis may be required. Oral ion exchange resins, such as sodium polystyrene sulfonate (SPS), have traditionally been used to bind and excrete gastrointestinal potassium. There are concerns, however, with regard to SPS’s lack of proven efficacy and safety, with a number of reports of intestinal necrosis associated with its use. Alternative cation exchanges have been developed and are currently being trialled, with the aim of providing more effective and safer alternatives for the treatment of hyperkalaemia.

Acid–base homeostasis
The pH of arterial plasma is normally 7.40, corresponding to an H+ concentration of 40 nmol/L, and under normal circumstances H+ concentrations do not vary outside the range of 37–45 nmol/L (pH 7.43–7.35). Abnormalities of acid–base balance can occur in a wide range of diseases. Increases in H+ concentration cause acidosis with a decrease in pH, whereas decreases in H+ concentration cause alkalosis with a rise in pH.

Functional anatomy and physiology
A variety of physiological mechanisms maintain pH of the ECF within narrow limits. The first is the action of blood and tissue buffers, of which the most important involves reaction of H+ ions with bicarbonate to form carbonic acid, which, under the
influence of the enzyme carbonic anhydrase (CA), dissociates to form CO2 and water:

\[
\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-\]

This buffer system is important because bicarbonate is present at a relatively high concentration in ECF (21–29 mmol/L), and two of its key components are under physiological control: CO2 by the lungs, and bicarbonate by the kidneys. These relationships are illustrated in Figure 14.10 (a form of the Henderson–Hasselbalch equation).

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brainstem stimulate ventilatory drive, reduce inhibition of ventilation, causing a rise in \(\text{PCO}_2\) and reduction in \(\text{pH}\), although it should be noted that this mechanism has limited capacity to change \(\text{pH}\) because hypoxia provides an alternative stimulus to drive ventilation.

The kidneys provide a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes, the kidneys have the long-term capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

## Renal control of acid–base balance

Regulation of acid–base balance occurs at several sites in the kidney. The proximal tubule reabsorbs about 85% of the filtered bicarbonate ions, through the mechanism for \(\text{H}^+\) secretion illustrated in Figure 14.3A. This is dependent on the enzyme carbonic anhydrase, both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity and is required to rescue filtered bicarbonate, but does not lead to significant acidification of the luminal fluid.

Distal nephron segments also have an important role in acid excretion. Hydrogen ions are secreted into the lumen by an \(\text{H}^+\)-ATPase in the intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells. The \(\text{H}^+\) ions are generated in the tubular cell from the hydration of \(\text{CO}_2\) to form carbonic acid, which dissociates into an \(\text{H}^+\) ion secreted luminally, and a bicarbonate ion that passes across the basolateral membrane into the blood. The secreted \(\text{H}^+\) ions contribute to the reabsorption of any residual bicarbonate present in the luminal fluid, by generating intracellular OH\(^-\) that reacts with \(\text{CO}_2\) to form \(\text{HCO}_3^-\), which exits across the basolateral membrane. However, \(\text{H}^+\) secretion also contributes net acid for removal from the body, bound to a variety of urinary buffers, of which phosphate and ammonia are the most important. Urinary buffers are required to prevent a reduction in urinary \(\text{pH}\), which would create an unfavourable gradient that would prevent further \(\text{H}^+\) secretion.

Filtered phosphate \((\text{HPO}_4^{2-})\) combines with \(\text{H}^+\) in the distal tubular lumen to form dihydrogen phosphate \((\text{H}_2\text{PO}_4^-)\), which is excreted in the urine with sodium. Ammonia \((\text{NH}_3)\) is generated within tubular cells by deamination of the amino acid glutamine by the enzyme glutaminase. The \(\text{NH}_3\) then reacts with secreted \(\text{H}^+\) in the tubular lumen to form ammonium \((\text{NH}_4^+)\), which becomes trapped in the luminal fluid and is excreted with chloride ions.

These two mechanisms remove approximately 1 mmol/kg of hydrogen ions from the body per day, which equates to the non-volatile acid load arising from the metabolism of dietary protein. The slightly alkaline plasma \(\text{pH}\) of 7.4 (\(\text{H}^+\) 40 mmol/L) that is maintained during health can be accounted for by the kidney’s ability to generate an acidic urine (typically \(\text{pH}\) 5–6 (\(\text{H}^+\) 1000–10 000 mmol/L), in which the net daily excess of metabolic acid produced by the body can be excreted.

### Presenting problems in acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed \(\text{pH}\) (such as altered cardiac and central nervous system function), or with secondary changes in respiration that occur as a response to the underlying metabolic change (such as Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the underlying cause rather than the acid–base abnormality itself. Frequently, acid–base disturbances only become evident when the venous plasma bicarbonate concentration is measured and found to be abnormal, or when blood gas analysis shows abnormalities in \(\text{pH}\), \(\text{PCO}_2\) or bicarbonate.

The most common patterns of abnormality in blood gas parameters are shown in Box 14.18. Note that the terms acidosis and alkalosis strictly refer to the underlying direction of the acid–base change, while acidemia and alkalemia more correctly refer to the net change present in the blood. Interpretation of arterial blood gases is also described on page 555.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in \(\text{PCO}_2\) is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of \(\text{CO}_2\), largely within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of long-term adjustments in acid secretory capacity. When the clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected (p. 367).

### Metabolic acidosis

Metabolic acidosis occurs when an acid other than carbonic acid (due to \(\text{CO}_2\) retention) accumulates in the body, resulting in a
Metabolic acidosis with a normal anion gap occurs when there is a primary loss of bicarbonate from the ECF, or when there is poisoning with or therapeutic infusion of a mineral acid such as hydrochloric acid or ammonium chloride. Renal tubular acidosis (RTA) is an important cause of metabolic acidosis with a normal anion gap. It can be caused by a defect in one of three processes:

- impaired bicarbonate reabsorption in the proximal tubule (proximal RTA)
- impaired acid secretion in the late distal tubule or cortical collecting duct intercalated cells (classical distal RTA)
- impaired sodium reabsorption in the late distal tubule or cortical collecting duct, which is associated with reduced secretion of both potassium and H⁺ ions (hyperkalaemic distal RTA).

Various subtypes of RTA are recognised and the most common causes are shown in Box 14.20. The inherited forms of RTA are due to mutations in the genes that regulate acid or bicarbonate transport in the renal tubules (see Fig. 14.3). Acidosis with an increased anion gap is most commonly seen in ketoacidosis, renal failure and lactic acidosis, where there is endogenous production of anions distinct from Cl⁻ and HCO₃⁻. Ketoacidosis is caused by insulin deficiency and is exacerbated by catecholamine and stress hormone excess, which combine to cause lipolysis and the formation of acidic ketones (acetoacetate, 3-hydroxybutyrate and acetone). The most common cause of ketoacidosis is diabetic ketoacidosis (DKA); its aetiology and management are discussed on page 735. Starvation ketoacidosis occurs when there is reduced food intake in situations of high glucose demand, such as in neonates, and in pregnant or breastfeeding women. In alcoholic ketoacidosis, there is usually a background of chronic malnutrition and a recent alcohol binge. Two subtypes of lactic acidosis have been defined:

- type 1, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock
- type 2, due to impaired metabolism of lactate, as in liver disease or by a number of drugs and toxins, including metformin, which inhibit lactate metabolism (p. 746).

Metabolic acidosis with an increased anion gap may also be a consequence of exogenous acid loads from poisoning with aspirin, methanol or ethylene glycol.
Clinical features

Normal anion gap metabolic acidosis is usually due either to bicarbonate loss in diarrhoea, where the clinical diagnosis is generally obvious, or to RTA. Although some forms of RTA are inherited, it may also be an acquired disorder, and in these circumstances the discovery of metabolic acidosis may serve as an early clue to the underlying diagnosis. The presentation of increased anion gap acidosis is usually dominated by clinical features of the underlying disease, such as uncontrolled diabetes mellitus, kidney failure or shock, or may be suggested by the clinical history of starvation, alcoholism or associated symptoms, such as visual complaints in methanol poisoning (p. 147).

Investigations

The different types of metabolic acidosis can be distinguished by blood gas measurements, along with measurements of creatinine, electrolytes and bicarbonate. Under normal circumstances, the anion gap, defined as the numerical difference between the main measured cations (Na\(^+\) + K\(^+\)) and the anions (Cl\(^-\) + HCO\(_3\)\(^-\)) is about 5–11 mmol/L. This gap is normally made up of anions, such as phosphate and sulphate, as well as albumin. RTA should be suspected when there is a hyperchloreaemic acidosis with a normal anion gap in the absence of gastrointestinal disturbance. The diagnosis can be confirmed by finding an inappropriately high urine pH (>5.5) in the presence of systemic acidosis. Sometimes, distal RTA may be incomplete, such that the plasma bicarbonate concentration may be normal under resting conditions. In this case, an acid challenge test can be performed by administration of an acid load in the form of ammonium chloride to reduce plasma bicarbonate. The diagnosis of incomplete distal RTA can be confirmed if the urine pH fails to fall below 5.3 in the presence of a low bicarbonate.

The different subtypes of RTA can be differentiated by various biochemical features. Patients with proximal and distal RTA often present with features of profound hypokalaemia, while type IV RTA is associated with hyperkalaemia. Proximal RTA is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi’s syndrome), as well as bicarbonate and potassium. Patients with this disorder can lower the urine pH when the acidosis is severe and plasma bicarbonate levels have fallen below 16 mmol/L, since distal H\(^+\) secretion mechanisms are intact. In the classical form of distal RTA, however, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and osteomalacia with hypercalcaemia, renal stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

Investigations in patients with raised anion gap metabolic acidosis show features of the underlying cause, such as reduced GFR in renal failure and raised urine or blood ketones in ketoacidosis. In DKA, blood glucose is raised, while in starvation and alcoholic acidosis blood glucose is not elevated and may be low. Measurement of plasma lactate is helpful in the diagnosis of lactic acidosis when values are increased over the normal maximal level of 2 mmol/L.

Management

The first step in management of metabolic acidosis is to identify and correct the underlying cause when possible (see Box 14.19). This may involve controlling diarrhoea, treating diabetes mellitus, correcting shock, stopping drugs that might cause the condition, or using dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with intravenous fluids is often needed. In alcoholism and starvation ketosis, intravenous glucose is indicated. By stimulating endogenous insulin secretion, this will reverse hepatic ketone production. Malnourished patients may also require thiamin, potassium, magnesium and phosphate supplements (p. 706). Use of intravenous bicarbonate in metabolic acidosis is controversial. Because rapid correction of acidosis can induce hypokalaemia or a fall in plasma ionised calcium, the use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and acidosis is severe (H\(^+\) > 100 mmol/L, pH < 7.00) or associated with evidence of tissue dysfunction.

The acidosis in RTA can sometimes be controlled by treating the underlying cause (see Box 14.20), but usually supplements of sodium and potassium bicarbonate are also necessary in types I and II RTA to achieve a target plasma bicarbonate level of > 18 mmol/L and normokalaemia. In type IV RTA, loop diuretics, thiazides or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in correcting the acidosis and the hyperkalaemia.

Metabolic alkalosis

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see Box 14.18). There is a compensatory rise in PCO\(_2\) due to hyperventilation but this is limited by the need to avoid hypoxia. Classical causes include primary hyperaldosteronism (Conn’s syndrome, p. 674), Cushing’s syndrome (p. 666) and glucocorticoid therapy (p. 670). Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

Pathophysiology

Metabolic alkalosis is best classified according to the accompanying changes in ECF volume. Hypovolaemic metabolic alkalosis is the most common pattern. This can be caused by sustained vomiting, in which acid-rich fluid is lost directly from the body, or by treatment with loop diuretics or thiazides. In the case of sustained vomiting, loss of gastric acid is the immediate cause of the alkalosis, but several factors act to sustain or amplify this in the context of volume depletion (Fig. 14.11). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering proximal sodium bicarbonate reabsorption and additional acid secretion by the distal tubule. Hypokalaemia occurs due to potassium loss in the vomitus and by the kidney as the result of secondary hyperaldosteronism, and itself is a stimulus to acid secretion. Additionally, the compensatory rise in PCO\(_2\) further enhances tubular acid secretion. The net result is sustained metabolic alkalosis with an inappropriately acid urine, which cannot be corrected until the deficit in circulating volume has been replaced.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when bicarbonate retention and volume expansion occur simultaneously.

Clinical features

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, however, plasma ionised calcium falls and signs of increased neuromuscular irritability, such as tetany, may develop (p. 663).

Investigations

The diagnosis can be confirmed by measurement of electrolytes and arterial blood gases.
Magnesium homeostasis

Respiratory alkalosis is usually of short duration, occurring in anxiety states or as the result of over-vigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease, and ingestion of certain drugs such as salicylates that directly stimulate the respiratory centre in the brainstem.

Clinical features are those of the underlying cause but agitation associated with perioral and digital tingling may also occur, as alkalosis promotes the binding of calcium to albumin, resulting in a reduction in ionised calcium concentrations. In severe cases, Trousseau’s sign and Chvostek’s sign may be positive, and tetany or seizures may develop (p. 663).

Management involves correction of identifiable causes, reduction of anxiety, and a period of rebreathing into a closed bag to allow CO₂ levels to rise.

Mixed acid–base disorders

It is not uncommon for more than one disturbance of acid–base metabolism to be present at the same time in the same patient: for example, a respiratory acidosis due to narcotic overdose with metabolic alkalosis due to vomiting. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the PCO₂ and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient’s acid–base status should be identified, and reference should be made to the table of predicted compensation given in Box 14.18. If the compensatory change is discrepant from the rules of thumb provided, more than one disturbance of acid–base metabolism may be suspected.

Calcium homeostasis

 Disorders of calcium homeostasis are discussed in Chapter 18 and bone disease is discussed in Chapter 24.

Magnesium homeostasis

Magnesium is mainly an intracellular cation. It is important to the function of many enzymes, including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

Functional anatomy and physiology

Renal handling of magnesium involves filtration of free plasma magnesium at the glomerulus (about 70% of the total), with extensive reabsorption (50–70%) in the loop of Henle and other parts of the proximal and distal renal tubule. Magnesium reabsorption is also enhanced by parathyroid hormone (PTH).

Presenting problems in magnesium homeostasis

Disturbances in magnesium homeostasis usually occur because of increased loss of magnesium through the gut or kidney or in plasma pH. If the condition is sustained, renal compensation occurs, such that tubular acid secretion is reduced and the plasma bicarbonate falls.
inability to excrete magnesium normally in patients with renal impairment.

### Hypomagnesaemia

Hypomagnesaemia is defined as existing when plasma magnesium concentrations are below the reference range of 0.75–1.0 mmol/L (1.5–2.0 mEq/L).

### Pathophysiology

Hypomagnesaemia usually is a reflection of magnesium depletion (Box 14.21), which can be caused by excessive magnesium loss from the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders, such as Gitelman’s and Bartter’s syndromes, can also result in urinary magnesium wasting (p. 361). Magnesium depletion has important effects on calcium homeostasis because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia causes end-organ resistance to PTH.

### Clinical features

Mild degrees of hypomagnesaemia may be asymptomatic but more severe hypomagnesaemia may be associated with symptoms of hypocalcaemia, such as tetany, cardiac arrhythmias (notably torsades de pointes, p. 476), central nervous excitation and seizures, vasoconstriction and hypertension. Hypomagnesaemia and magnesium depletion are also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may contribute to some of the clinical manifestations.

### Management

The underlying cause should be identified and treated where possible. When symptoms are present, the treatment of choice is intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. If intravenous access is not feasible, magnesium sulphate can be given intramuscularly. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. If hypomagnesaemia is caused by diuretic treatment, adjunctive use of a potassium-sparing agent can also help by reducing magnesium loss into the urine.

### Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. Predisposing conditions include acute kidney injury, chronic kidney disease and adrenocortical insufficiency. The condition is generally precipitated in patients at risk from an increased intake of magnesium, or from the use of magnesium-containing medications, such as antacids, laxatives and emenae.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium-containing drugs and reducing dietary magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to ameliorate cardiac effects. Dialysis may be necessary in patients with poor renal function.

### Phosphate homeostasis

Inorganic phosphate (mainly present as HPO$_4^{2-}$) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral homeostasis (Ch. 24). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–3.4 mg/dL).

**Functional anatomy and physiology**

Phosphate is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, through an apical sodium–phosphate co-transport carrier. A further 10–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as H$_2$PO$_4^-$ . Proximal reabsorption is decreased by PTH, fibroblast growth factor 23 (FGF23), volume expansion, osmotic diuretics and glucose infusion.

**Presenting problems in phosphate homeostasis**

The following section deals primarily with conditions that cause acute disturbances in serum phosphate concentrations. Chronic disorders that are accompanied by phosphate depletion, such as osteomalacia and hypophosphataemic rickets, are discussed in Chapter 24. Acute kidney injury and chronic kidney disease, which are associated with hyperphosphataemia, are discussed below and also in Chapter 15.

### Hypophosphataemia

Hypophosphataemia is defined as existing when serum phosphate values fall below 0.8 mmol/L (2.48 mg/dL). The causes are shown in Box 14.22, subdivided into the underlying pathogenic mechanisms.
Pathophysiology

Phosphate may redistribute into cells during periods of increased energy utilisation (such as refuelling after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due to either inadequate intake or absorption through the gut, or excessive renal losses, most notably in primary hyperparathyroidism (p. 663) or as the result of acute plasma volume expansion, osmotic diuresis and diuretics acting on the proximal renal tubule. Less common causes include inherited defects of proximal sodium–phosphate co-transport and tumour-induced osteomalacia due to ectopic causes.

Clinical features

The clinical features of phosphate depletion are wide-ranging, reflecting the involvement of phosphate in many aspects of metabolism. Defects appear in the blood (impaired function and survival of all cell lineages), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia in severe prolonged hypophosphataemia, p. 1053).

Investigations

Measurement of creatinine, electrolytes, phosphate, albumin, calcium and alkaline phosphatase should be performed. In selected cases, measurement of PTH and 25(OH)D may be helpful to exclude osteomalacia or hypophosphataemic rickets. The combination of hypophosphataemia and hypercalcaemia suggests primary hyperparathyroidism, which should be further investigated by measurements of PTH, as described on page 663. The presence of hypercalcaemia suggests hypophosphataemic rickets, which should be further investigated as described on page 1053.

Management

Management of hypophosphataemia due to decreased dietary intake or excessive losses involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements that are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification. Management of primary hyperparathyroidism and hypophosphataemic rickets are described in more detail on pages 664 and 1053.

Hyperphosphataemia

Hyperphosphataemia is most commonly caused by acute kidney injury or chronic kidney disease (pp. 413 and 419).

Pathophysiology

In acute kidney injury and chronic kidney disease, the primary cause is reduced phosphate excretion as the result of a low GFR. In contrast, the hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism is due to increased tubular phosphate reabsorption. Redistribution of phosphate from cells into the plasma can also be a contributing factor in the tumour lysis syndromes and other catabolic states. Phosphate accumulation can be aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

Clinical features

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic kidney disease with tertiary hyperparathyroidism (when a high calcium–phosphate product occurs).

Management

Hyperphosphataemia in patients with kidney disease should be treated with dietary phosphate restriction and the use of oral phosphate binders (p. 418). Hyperphosphataemia in hypoparathyroidism and pseudohypoparathyroidism does not usually require treatment. Hyperphosphataemia associated with tumour lysis syndromes and catabolic states can be treated with intravenous normal saline, which is given to promote phosphate excretion.

Disorders of amino acid metabolism

Congenital disorders of amino acid metabolism usually present in the neonatal period and may involve life-long treatment regimens. However, some disorders, particularly those involved in amino acid transport, may not present until later in life.

Phenylketonuria

Phenylketonuria (PKU) is inherited as an autosomal recessive disorder caused by loss-of-function mutations in the PAH gene, which encodes phenylalanine hydroxylase, an enzyme required for degradation of phenylalanine. As a result, phenylalanine accumulates at high levels in the neonate’s blood, causing intellectual disability. The diagnosis of PKU is almost always made by routine neonatal screening (p. 56). Treatment involves life-long adherence to a low-phenylalanine diet. Early and adequate dietary treatment prevents major intellectual disability, although there may still be a slight reduction in IQ.

Homocystinuria

Homocystinuria is an autosomal recessive disorder caused by loss-of-function mutations in the CBS gene, which encodes cystathionine β-synthase. The enzyme deficiency causes accumulation of homocysteine and methionine in the blood. Many cases of homocystinuria are diagnosed through newborn screening programmes.
Clinical manifestations are wide-ranging and involve the eyes (ectopia lentis – displacement of the lens), central nervous system (intellectual disability, delayed development milestones, seizures, psychiatric disturbances), skeleton (resembling Marfan’s syndrome, and also with generalised osteoporosis), vascular system (thrombotic lesions of arteries and veins) and skin (hypopigmentation).

Treatment is dietary, involving a methionine-restricted, cystine-supplemented diet, as well as large doses of pyridoxine.

### Disorders of carbohydrate metabolism

The most common disorder of carbohydrate metabolism is diabetes mellitus, which is discussed in Chapter 20. There are also some rare inherited defects, discussed below.

#### Galactosaemia

Galactosaemia is caused by loss-of-function mutations in the GALT gene, which encodes galactose-1-phosphate uridyl transferase. It is usually inherited in an autosomal recessive manner. The neonate is unable to metabolise galactose, one of the hexose sugars contained in lactose. Vomiting or diarrhoea usually begins within a few days of ingestion of milk, and the neonate may become jaundiced. Failure to thrive is the most common clinical presentation. The classic form of the disease results in hepatomegaly, cataracts and intellectual disability. Fulminant infection with *Escherichia coli* is a frequent complication. Treatment involves life-long avoidance of galactose- and lactose-containing foods.

The widespread inclusion of galactosaemia in newborn screening programmes has resulted in the identification of a number of milder (‘Duarte’) variants.

#### Glycogen storage diseases

Glycogen storage diseases (GSDs, or glycogenoses) result from inherited defects in one of the many enzymes responsible for the formation or breakdown of glycogen, a complex carbohydrate that can be broken down quickly to release glucose during exercise or between meals.

There are several major types of GSD, which are classified by a number, by the name of the defective enzyme, or eponymously after the physician who first described the condition (Box 14.23). Most forms of GSD are inherited in an autosomal recessive manner.

The diagnosis of GSD is made on the basis of the symptoms, physical examination and results of biochemical tests. Occasionally, a muscle or liver biopsy is required to confirm the enzyme defect. Different types of GSD present at different ages, and some may require life-long modifications of diet and lifestyle.

#### Disorders of complex lipid metabolism

Complex lipids are key components of the cell membrane that are normally catabolised in organelles called lysosomes. The lysosomal storage diseases are a heterogeneous group of disorders caused by loss-of-function mutations in various lysosomal enzymes (Box 14.24), resulting in an inability to break down complex glycolipids or other intracellular macromolecules. These disorders have diverse clinical manifestations, typically including intellectual disability. Some can be treated with enzyme replacement therapy, while others (such as Tay–Sachs disease) can be prevented through community participation in genetic carrier screening programmes.

#### Lipids and lipoprotein metabolism

The three main biological classes of lipid are:

- cholesterol, which is composed of hydrocarbon rings
- triglycerides (TGs), which are esters composed of glycerol linked to three long-chain fatty acids
- phospholipids, which are composed of a hydrophilic ‘tail’ consisting of two long-chain fatty acids linked through glycerol to a hydrophilic head containing a phosphate group.

Phospholipids are present in cell membranes and are important signalling molecules.

Despite their poor water solubility, lipids need to be absorbed from the gastrointestinal tract and transported throughout the body. This is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TGs are clinically important because they are major treatable risk factors for cardiovascular disease, while severe hypertriglyceridaemia also predisposes to acute pancreatitis.

**Functional anatomy and physiology**

Lipids are transported and metabolised by apolipoproteins, which combine with lipids to form spherical or disc-shaped lipoproteins, consisting of a hydrophobic core and a less hydrophobic coat (Fig. 14.12). The structure of some apolipoproteins also enables them to act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

**Processing of dietary lipid**

The intestinal absorption of dietary lipid is described on page 768 (see also Fig. 14.13). Enterocytes lining the gut extract monoglyceride and free fatty acids from micelles and re-esterify them into TGs, which are combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol derived from dietary and biliary sources is also absorbed through a specific intestinal membrane transporter termed NPC1L1. This produces chylomicrons containing TG and cholesterol ester that are secreted basolaterally into lymphatic lacteals and carried to the circulation through the thoracic duct.

On entering the blood stream, nascent chylomicrons are modified by further addition of apolipoproteins. Chylomicron TGs are hydrolysed by lipoprotein lipase located on the endothelium of tissue capillary beds. This releases fatty acids that are used locally for energy production or stored as TG in muscle or fat. The residual ‘remnant’ chylomicron particle is avidly cleared by low-density lipoprotein receptors (LDLRs) in the liver, which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are usually undetectable in the plasma after a 12-hour fast.

The main dietary determinants of plasma cholesterol concentrations are the intake of saturated and trans-unsaturated fatty acids, which reduce LDLR levels (see below), whereas dietary cholesterol has surprisingly little effect on fasting cholesterol levels. Plant sterols and drugs that inhibit cholesterol absorption are effective because they also reduce the re-utilisation of biliary cholesterol. The dietary determinants of plasma TG concentrations are complex since excessive intake of carbohydrate, fat or alcohol may all contribute to increased plasma TG by different mechanisms.

**Endogenous lipid synthesis**

In the fasting state, the liver is the major source of plasma lipids (Fig. 14.13). The liver may acquire lipids by uptake, synthesis or conversion from other macronutrients. These lipids are transported to other tissues by secretion of very low-density lipoproteins (VLDLs), which are rich in TG but differ from chylomicrons in that they are less massive and contain full-length Apo B100. Following secretion into the circulation, VLDLs undergo metabolic processing similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDLs into ‘remnant’ particles, referred to as intermediate-density lipoproteins (IDLs). Most IDLs are rapidly cleared by LDLRs in the liver but some are
Cholesterol transport

Peripheral tissues are further guarded against excessive cholesterol accumulation by high-density lipoproteins (HDLs; Fig. 14.13). Lipid-poor Apo A1 (derived from the liver, intestine and the outer layer of chylomicrons and VLDL) accepts cellular cholesterol and phospholipid from a specific membrane transporter known as the ATP-binding cassette A1 (ABCA1). This produces small HDLs that are able to accept more free cholesterol from cholesterol-rich regions of the cell membrane known as ‘rafts’ via another membrane transporter (ABCG1). The cholesterol that has been accepted by these small HDLs is esterified by lecithin cholesterol acyl transferase (LCAT), thus maintaining an uptake gradient and of the half-life of LDLR through PCSK9, and modulation of cholesterol esterification.

**Fig. 14.13** Absorption, transport and storage of lipids. Pathways of lipid transport are shown; in addition, cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between very low-density lipoprotein/chylomicrons and high-/low-density lipoprotein, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1/ABCG1 = adenosine triphosphate-binding cassette A1/G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-co-enzyme A reductase; IDL = intermediate-density lipoprotein; iHDL = immature high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; PCSK9 = proprotein convertase subtilisin kexin 9; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)”
remodelling the particle into a mature spherical HDL. These HDLs release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1).

The cholesterol ester transfer protein (CETP) in plasma allows transfer of cholesterol from HDLs or LDLs to VLDls or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDLs into ‘small, dense’ LDL particles that may be more atherogenic in the blood-vessel wall. Animal species that lack CETP are resistant to atherosclerosis.

**Lipids and cardiovascular disease**

Plasma lipoprotein levels are major modifiable risk factors for cardiovascular disease. Increased levels of atherogenic lipoproteins (especially LDL, but also IDL, and possibly chylomicron remnants) contribute to the development of atherosclerosis (p. 484). A sub-population of LDL particles bears an additional protein known as apolipoprotein (a), which shares homology with plasminogen. The combination of LDL and apolipoprotein (a) is known as lipoprotein (a) (Lp(a)). It transports oxidised phospholipid and is regarded as atherogenic because its plasma concentration is an independent risk factor for cardiovascular disease. Following chemical modifications such as oxidation, Apo B-containing lipoproteins are no longer cleared by normal mechanisms. They trigger a self-perpetuating inflammatory response, during which they are taken up by macrophages to form foam cells, a hallmark of atherosclerotic lesions. These processes also have an adverse effect on endothelial function.

Conversely, HDL removes cholesterol from the tissues to the liver, where it is metabolised and excreted in bile. HDL may also counteract some components of the inflammatory response, such as the expression of vascular adhesion molecules by the endothelium. Consequently, low HDL cholesterol levels, which are often associated with TG elevation, are also associated with atherosclerosis.

**Investigations**

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of cardiovascular disease
- investigation of patients with clinical features of lipid disorders (p. 347) and their relatives
- monitoring of response to diet, weight control and medication.

Abnormalities of lipid metabolism most commonly come to light following these tests. Non-fasting measurements of total cholesterol (TC) and HDL cholesterol (HDL-C) allow estimation of non-HDL cholesterol (non-HDL-C, calculated as TC–HDL-C), but a 12-hour fasting sample is required to standardise TG measurement and allow calculation of LDL cholesterol (LDL-C) according to the Friedewald formula:

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/2.2) \text{mmol/L}$$

or

$$\text{LDL-C} = \text{TC} - \text{HDL-C} - (\text{TG}/5) \text{mg/dL}$$

The formula becomes unreliable when TG levels exceed 4 mmol/L (350 mg/dL). Measurements of non-HDL-C or Apo B100 may assess risk of cardiovascular disease more accurately than LDL-C, particularly when TG levels are increased. The use of non-fasting samples is increasing because non-fasting TG is a more sensitive marker of the risk of cardiovascular disease. Nevertheless, a 12-hour fast is required for formal diagnosis of the presence of hypertriglyceridaemia or use of the Friedewald equation. Consideration must be given to confounding factors, such as recent illness, after which cholesterol, LDL and HDL levels temporarily decrease in proportion to severity. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Elevated levels of TG are common in obesity, diabetes and insulin resistance (Chs 19 and 20), and are frequently associated with low HDL and increased ‘small, dense’ LDL. Under these circumstances, LDL-C may under-estimate risk. This is one situation in which measurement of non-HDLC or Apo B may provide more accurate risk assessment.

**Presenting problems in lipid metabolism**

Hyperlipidaemia can occur in association with various diseases and drugs, as summarised in Box 14.25. Overt or subclinical hypothyroidism (p. 639) may cause hypercholesterolaemia, and so measurement of thyroid function is warranted in most cases, even in the absence of typical symptoms and signs.

Once secondary causes are excluded, primary lipid abnormalities may be diagnosed. Primary lipid abnormalities can be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 14.26). Although single-gene disorders are encountered in all three categories, most cases are due to multiple-gene (polygenic) loci interacting with environmental factors. Clinical consequences of dyslipidaemia vary somewhat between these causes (pp. 346–347).

**Hypercholesterolaemia**

Hypercholesterolaemia is a polygenic disorder that is the most common cause of a mild to moderate increase in

**14.27 Familial hypercholesterolaemia in adolescence**

- **Statin treatment:** may be required from the age of about 10. It does not compromise normal growth and maturation.
- **Smoking:** patients should be strongly advised not to smoke.
- **Adherence to medication:** critically important to the success of treatment. Simple regimens should be used and education and support provided.

LDL-C (Box 14.26). Physical signs, such as corneal arcus and xanthelasma, may be found in this as well as other forms of lipid disturbance (p. 346). The risk of cardiovascular disease is proportional to the degree of LDL-C (or Apo B) elevation, but is modified by other major risk factors, including low HDL-C and high Lp(a).

Familial hypercholesterolaemia (FH) is a more severe disorder with a prevalence of at least 0.4% in most populations. It is usually caused by loss-of-function mutations affecting the LDLR gene, which results in an autosomal dominant pattern of inheritance. A similar syndrome can arise with loss-of-function mutations in the ligand-binding domain of Apo B100 or gain-of-function mutations in PCSK9, which promote LDLR degradation. Causative mutations can be detected in one of these three genes by genetic testing in about 70% of patients with FH. Most patients with these types of FH have LDL-C levels that are approximately twice as high as in normal subjects of the same age and gender. Affected patients suffer from severe hypercholesterolaemia and premature cardiovascular disease. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (p. 346), which are strongly suggestive of FH. The onset of corneal arcus before age 40 is also suggestive of this condition. Identification of an index case of FH (the first case of FH in a family) should trigger genetic and biochemical screening of other family members, which is a cost-effective method for case detection. Affected individuals should be managed from childhood (Box 14.27).

Homozygous FH may occur sporadically, especially in populations in which there is a ‘founder’ gene effect or consanguineous marriage. Homozygosity results in more extensive xanthomas and precocious cardiovascular disease, often in childhood. Hyperalphalipoproteinaemia refers to increased levels of HDL-C. In the absence of an increase in LDL-C, this condition rarely causes cardiovascular disease, but exceptions can occur so it should not be regarded as universally benign.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypercholesterolaemia (see ‘Mixed hyperlipidaemia’ below).

**Hypertriglyceridaemia**

Hypertriglyceridaemia also usually involves polygenic factors (see Box 14.26). Other common causes include excess alcohol intake, medications (such as β-blockers and retinoids), type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 728) and impaired absorption of bile acids. It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to cardiovascular risk. Excessive intake of alcohol or dietary fat, or other exacerbating factors, may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Monogenic forms of hypertriglyceridaemia also occur due to loss-of-function mutations in the genes encoding lipoprotein lipase, Apo C2 or ANGPTL4, which coordinate the lipolytic breakdown of TG-rich lipoproteins. These cause recessively inherited forms of severe hypertriglyceridaemia that is not readily amenable to drug treatment. They can present in childhood and may be associated with episodes of acute abdominal pain and pancreatitis. In common with other causes of severe hypertriglyceridaemia, hepatomegaly, lipoaemia retinalis and eruptive xanthomas may occur (p. 346). Familial hypertriglyceridaemia may also be inherited in a dominant manner due to mutations in the APOA5 gene, which encodes Apo A5 – a co-factor that is essential for lipoprotein lipase activity. These disorders may also be associated with increased risk of cardiovascular disease.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypertriglyceridaemia (see ‘Mixed hyperlipidaemia’, below).
Mixed hyperlipidaemia

It is difficult to define quantitatively the distinction between predominant hyperlipidaemias and mixed hyperlipidaemia. The term ‘mixed’ usually implies the presence of hypertriglyceridaemia, as well as an increase in LDL-C or IDL. Treatment of massive hypertriglyceridaemia may improve TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often occurs in association with type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 728). Both components of mixed hyperlipidaemia may contribute to the risk of cardiovascular disease.

Familial combined hyperlipidaemia is a term used to identify an inherited tendency towards the over-production of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of cardiovascular disease but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps insulin resistance.

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of roughly equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDLR. In conjunction with other exacerbating factors, such as obesity or diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature cardiovascular disease is common, as is peripheral vascular disease. It may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

Rare dyslipidaemias

Several rare disturbances of lipid metabolism have been described (Box 14.28). They provide important insights into lipid metabolism and its impact on risk of cardiovascular disease.

Fish eye disease, Apo A1 Milano and lecithin cholesterol acyl transferase (LCAT) deficiency demonstrate that very low HDL-C levels do not necessarily cause cardiovascular disease, but Apo A1 deficiency, and possibly Tangier disease, demonstrate that low HDL-C can be atherogenic under some circumstances. Autosomal recessive FH and PCSK9 gain-of-function mutations reveal the importance of proteins that chaperone the LDLR. Stiosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and cardiovascular disease, while PCSK9 loss-of-function mutations, abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of cardiovascular disease. The only adverse health outcomes associated with extremely low plasma lipid levels in the latter two conditions are attributable to fat-soluble vitamin deficiency, or impaired transport of lipid from intestine or liver.

Principles of management

Lipid-lowering therapies have a key role in the secondary and primary prevention of cardiovascular diseases (p. 487). Assessment of absolute risk of cardiovascular disease, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and exercise, are central to management in all cases. Patients with the greatest absolute risk of cardiovascular disease derive the greatest absolute benefit from treatment. Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables such as the Joint British Societies Coronary Risk Prediction Chart (see Fig. 16.77, p. 511). These tables, which are based on large epidemiological studies, should be recalibrated for the local population, if possible.

In general, patients who have cardiovascular disease, diabetes mellitus, chronic renal impairment, familial hypercholesterolaemia or an absolute risk of cardiovascular disease of more than 20% in the ensuing 10 years are arbitrarily regarded as having sufficient risk to justify drug treatment. Age is such an overwhelming determinant of absolute cardiovascular risk that some recent recommendations consider ‘lifetime’ risk. This diminishes the pressure to treat very elderly patients and supports earlier intervention in non-elderly patients.

Public health organisations also recommend target levels for patients receiving drug treatment. High-risk patients should aim for HDL-C >1 mmol/L (38 mg/dL) and fasting TG <2 mmol/L (approximately 180 mg/dL), while target levels for LDL-C have been reduced to 1.8 mmol/L (76 mg/dL) or less. In general, total cholesterol should be <5 mmol/L (190 mg/dL) during treatment, and <4 mmol/L (approximately 150 mg/dL) in high-risk patients and in secondary prevention of cardiovascular disease. Recent trials have demonstrated continuous benefit of LDL-C reduction to a level of 1.4 mmol/L (54 mg/dL), so further reduction in treatment targets may be anticipated.

Non-pharmacological management

Patients with lipid abnormalities should receive medical advice and, if necessary, dietary counselling to:

• reduce intake of saturated and trans-unsaturated fat to less than 7–10% of total energy
• reduce intake of cholesterol to <250 mg/day
• replace sources of saturated fat and cholesterol with alternative foods, such as lean meat, low-fat dairy

| 14.28 Miscellaneous and rare forms of hyperlipidaemia |

| LCAT deficiency | Very low HDL, high TG | ? |
| Autosomal recessive FH | Very high LDL | ++ |
| Sitosterolaemia | High plant sterols including sitosterol | + |
| Cerebrotendinous xanthomatosis | Bile acid defect (cholesterol accumulation) | + |

+ = slightly increased risk; ++ = increased risk.

(CVD = cardiovascular disease; FH = familial hypercholesterolaemia; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; TC = total cholesterol; TG = triglycerides)
products, polyunsaturated spreads and low-glycaemic-index carbohydrates
- reduce energy-dense foods such as fats and soft drinks, while increasing activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods, such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes, and fruit
- adjust alcohol consumption, reducing intake if excessive or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with preferential intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols.

The response to diet is usually apparent within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine clinical practice. Explanation, encouragement and persistence are often required to assist patient adherence. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients (p. 700).

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

## Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatment (Fig. 14.14).

### Hypercholesterolaemia

Hypercholesterolaemia can be treated with one or more of the cholesterol-lowering drugs as described below.

#### Statins

These reduce cholesterol synthesis by inhibiting the HMGCoA reductase enzyme. The reduction in cholesterol synthesis up-regulates production of the LDLR, which increases clearance of LDL and its precursor, IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by up to 10%. They also reduce the concentration of intermediate metabolites such as isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events across the spectrum of cardiovascular disease risk.

Statins are generally well tolerated and serious side-effects are rare (well below 2%). Liver function test abnormalities and muscle problems, such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis, are the most common. Side-effects are more likely in patients who are elderly, debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

#### Ezetimibe

Ezetimibe inhibits activity of the intestinal mucosal transporter NPC1L1, which is responsible for absorption of dietary and biliary cholesterol. The resulting depletion of hepatic cholesterol up-regulates hepatic LDLR production. This mechanism of action is synergistic with the effect of statins. Monotherapy in a 10 mg/day dose reduces LDL-C by 15–20%. Slightly greater (17–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins. Ezetimibe is well tolerated, and evidence of a beneficial effect on cardiovascular disease endpoints is now available. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7–15%.

#### Bile acid-sequestering resins

Drugs in this class include colestyramine, colestipol and colesevelam. These prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. As with ezetimibe, the resultant depletion of hepatic cholesterol up-regulates LDL receptor activity and reduces LDL-C in a manner that is synergistic with the action of statins. Resins reduce LDL-C and modestly increase HDL-C, but may increase TG. They are safe but may interfere with bioavailability of other drugs. Colesevelam has fewer gastrointestinal effects than older

---

**Fig. 14.14 Flow chart for the drug treatment of hyperlipidaemia.** Interrupt treatment if creatine kinase is more than 5–10 times the upper limit of normal, or if elevated with muscle symptoms, or if alanine aminotransferase is more than 2–3 times the upper limit. To convert triglyceride (TG) in mmol/L to mg/dL, multiply by 88. To convert low-density lipoprotein (LDL)-C in mmol/L to mg/dL, multiply by 38.
preparations that are less well tolerated. The depletion of bile acids is sensed via the farnesyl X receptor and the response may also improve glucose metabolism.

**PCSK9 inhibitors**

Monoclonal antibodies have been developed that neutralise PCSK9, an enzyme that degrades the LDLR. This causes levels of LDLR to increase, which markedly reduces LDL-C. The PCSK9 inhibitors currently available are evolocumab and alirocumab, which are administered by subcutaneous injection every 2–4 weeks. These drugs are well tolerated and highly effective. Reductions in LDL-C of about 50–60% have been observed in patients who have not responded adequately to standard lipid-lowering therapy and this has been accompanied by a reduction in the risk of cardiovascular events of about 15%. The PCSK9 inhibitors do not deplete intracellular concentrations and, because of that, do not trigger compensatory mechanisms that blunt the effect of other cholesterol-lowering medications.

**Nicotinic acid**

Pharmacological doses reduce peripheral fatty acid release, with the result that VLDL and LDL decline while HDL-C increases. Recent randomised clinical trials have been disappointing regarding effects on atherosclerosis and cardiovascular events. The same may be said of novel agents that inhibit cholesterol ester transfer protein. Neither of these HDL-C-raising drugs is indicated in current lipid management.

**Combination therapy**

In many patients, treatment of predominant hypercholesterolaemia can be achieved by diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL targets on the highest tolerated statin dose, or who are intolerant of statins, may receive ezetimibe, plant sterols, or resins. Ezetimibe and resins are safe and effective in combination with a statin because of the mechanisms of action of individual therapies complement each other while blunting each other’s compensatory mechanisms.

**Hypertriglyceridaemia**

Predominant hypertriglyceridaemia can be treated with one of the TG-lowering drugs described below (see Fig. 14.14).

**Fibrates**

These stimulate peroxisome proliferator-activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of TG and HDL. As a result, synthesis of fatty acids, TG and VLDL is reduced, while that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ABC A1 is up-regulated, leading to increased reverse cholesterol transport via HDL. Consequently, fibrates reduce TG by up to 50% and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins. The results are less conclusive, but reduced rates of cardiovascular disease have been reported with fibrate therapy in the subgroup of patients with low HDL-C levels and elevated TG (TG >2.3 mmol/L (200 mg/dL)). Fibrates are usually well tolerated but share a similar side-effect profile to statins. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants. Accumulating evidence suggests that they may also have a protective effect against diabetic microvascular complications.

**Mixed hyperlipidaemia**

Mixed hyperlipidaemia can be difficult to treat. First-line therapy with statins alone is unlikely to achieve target levels once fasting TGs exceed approximately 4 mmol/L (350 mg/dL). Fibrates...
are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include:

- statin plus fenofibrate (recognising that the risk of myopathy is increased with gemfibrozil, but fenofibrate is relatively safe in this regard)
- statin plus fish oil when TG is not too high
- fibrate plus ezetimibe when cholesterol is not too high.

**Monitoring of therapy**

The effects of lipid-lowering therapy should be assessed after 6 weeks (12 weeks for fibrates). At this point, it is prudent to review side-effects, lipid response (see target levels above), CK and liver function tests. During longer-term follow-up, adherence to treatment, diet and exercise should be assessed, with monitoring of weight, blood pressure and lipid levels. The presence of cardiovascular symptoms or signs should be noted and absolute cardiovascular risk assessed periodically. Effective statin therapy may be associated with a paradoxical and as yet unexplained increase in coronary calcium score.

It is not necessary to perform routine checks of CK and liver function unless symptoms occur, or if statins are used in combination with fibrates, or other drugs that may interfere with their clearance. If myalgia or weakness occurs in association with CK elevation over 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation more than 2–3 times the upper limit of normal occurs that is not accounted for by fatty liver (p. 882), treatment should be discontinued and alternative therapy sought.

The principles of the management of dyslipidaemia can be applied broadly, but the objectives of treatment in the elderly (Box 14.29) and the safety of pharmacological therapy in pregnancy (Box 14.30) warrant special consideration.

**The porphyrias**

This group of disorders is caused by inherited abnormalities in the haem biosynthetic pathway (Fig. 14.15). Most of the described forms are due to partial enzyme deficiencies with a dominant mode of inheritance. They are commonly classified as hepatic or erythropoietic, depending on whether the major site of excess porphyrin production is in the liver or red cell.

The porphyrias have a penetrance in the order of 25%, emphasising the importance of environmental factors in disease expression. In porphyria cutanea tarda (PCT), which is the most
common cause of porphyria, environmental triggers include alcohol, iron accumulation, exogenous oestrogens and exposure to various chemicals. Many cases are associated with hepatitis C infection and this should always be screened for on presentation.

**Clinical features**

The clinical features of porphyria fall into two broad categories: photosensitivity and acute neurovisceral syndrome. The enzyme defects responsible for the diseases are shown in Figure 14.15.

Photosensitive skin manifestations, attributable to excess production and accumulation of porphyrins in the skin, cause pain, erythema, bullae, skin erosions, hirsutism and hyperpigmentation, and occur predominantly on areas of the skin that are exposed to sunlight (p. 1220). The skin also becomes sensitised to damage from minimal trauma.

The other pattern of presentation is with an acute neurological syndrome. This almost always presents with acute abdominal pain together with features of autonomic dysfunction, such as tachycardia, hypertension and constipation. Neuropsychiatric manifestations, hyponatraemia due to inappropriate ADH release (p. 357), and an acute neuropathy may also occur (p. 1138). The neuropathy is predominantly motor and may, in severe cases, progress to respiratory failure.

There is no proven explanation for the episodic nature of the attacks in porphyria, which can relapse and remit or follow a prolonged and unremitting course. Sometimes, specific triggers can be identified, such as alcohol, fasting, or drugs such as anticonvulsants, sulphonamides, oestrogen and progesterone. The oral contraceptive pill is a common precipitating factor. In a significant number, no precipitant can be identified.

**Investigations**

The diagnosis of porphyria and classification into the various forms have traditionally relied on measurements of porphyrins and porphyrin precursors found in blood, urine and faeces (Box 14.31). The diagnosis is straightforward when the metabolites are significantly elevated, but this is not always the case in asymptomatic individuals who may have normal porphyrin studies. More recently, measurement of the enzymes that are deficient in the various porphyrias has provided further diagnostic information.

An example is measurement of porphobilinogen deaminase activity in red blood cells to diagnose acute intermittent porphyria. There is often considerable overlap between enzyme activities in affected and normal subjects, however. Furthermore, some of the enzymes occur in the mitochondria, for which it is more difficult to obtain suitable specimens for analysis. All the genes of the haem biosynthetic pathway have now been characterised. This has made it possible to identify affected individuals in families by genetic testing, a significant advance considering that penetrance of porphyria is low.

Metabolite excretory patterns are always grossly abnormal during an acute attack or with cutaneous manifestations of porphyria, and are diagnostic of the particular porphyria. A normal metabolite profile under these circumstances effectively excludes porphyria. Metabolites usually remain abnormal for long periods after an acute attack, and in some individuals never return to normal. The diagnosis is not so straightforward in patients who are in remission, or in asymptomatic individuals with a positive family history. Neurological porphyria rarely manifests before puberty, nor can it be readily diagnosed after the menopause as porphyrin excretion may be normal. Genetic testing for disease-specific mutations can clarify the situation.

**Management**

For patients predisposed to neurovisceral attacks, general management includes avoidance of any agents known to precipitate acute porphyria. Specific management includes intravenous glucose, as provision of 5000 kJouloues per day can, in some cases, terminate acute attacks through a reduction in δ-aminolaevulinic acid (ALA) synthetase activity, leading to reduced ALA and porphyrin synthesis. More recently, administration of haem (in various forms such as haematin or haem arginate) has been shown to reduce metabolite excretory rates, relieve pain and accelerate recovery. Cyclical acute attacks in women sometimes respond to suppression of the menstrual cycle using gonadotrophin-releasing hormone analogues. In rare cases with frequent prolonged attacks or attacks intractable to treatment, liver transplantation has been effective.

There are few specific or effective measures to treat the photosensitive manifestations. The primary goal is to avoid sun exposure and skin trauma. Barrier sun creams containing zinc or titanium oxide are the most effective products. New colourless creams containing nanoparticle formulations have improved patient acceptance. Beta-carotene is used in some patients with erythropoietic porphyria with some efficacy. Afamelanotide, a synthetic analogue of alpha-melanocyte stimulating hormone (α-MSH), has also been shown to provide protection in erythropoietic protoporphyria, and is now undergoing approval in many countries. In porphyria cutanea tarda, a course of venesections to remove iron can result in long-lasting clinical and biochemical remission.

especially if exposure to identified precipitants, such as alcohol or oestrogens, is reduced. Alternatively, a prolonged course of low-dose chloroquine therapy is effective.

Clinical examination of the kidney and urinary tract

Many diseases of the kidney and urinary tract are clinically silent, at least in the early stages. Accordingly, it is common for these conditions to be detected first by routine blood tests or on dipstick testing of the urine. Several important abnormalities can also be picked up on physical examination, however, and these are summarised below.

1. **Hands**
   - Splinter haemorrhages
   - ‘Brown line’ pigmentation of nails

2. **Skin**
   - Yellow complexion*
   - Bruising*
   - Excoriation of pruritus*
   - Reduced skin turgor in fluid depletion

3. **Blood pressure**
   - Often elevated

4. **Jugular venous pressure**
   - Elevated in fluid overload

5. **Fundoscopy**
   - Hypertensive changes

6. **Lungs**
   - Crepitations in fluid overload

7. **Heart**
   - Extra heart sounds in fluid overload
   - Pericardial friction rub*

8. **Abdomen**
   - Renal mass
   - Local tenderness
   - Renal or other arterial bruits in renal vascular disease
   - Rectal examination — prostate

9. **Genitalia**
   - Scrotal swellings

10. **Sacral oedema**

11. **Ankle oedema**

12. **Peripheral neuropathy***

Male lower urinary tract demonstrating the relationship of the bladder, urethra, vas deferens and testes.
This chapter describes the disorders of the kidneys and urinary tract that are commonly encountered in routine practice, as well as giving an overview of the highly specialised field of renal replacement therapy. Disorders of renal tubular function, which may cause alterations in electrolyte and acid–base balance, are described in Chapter 14.

Functional anatomy and physiology

The kidneys

The kidneys play a central role in excretion of many metabolic breakdown products, including ammonia and urea from protein, creatinine from muscle, uric acid from nucleic acids, drugs and toxins. They achieve this by making large volumes of an ultrafiltrate of plasma (120 mL/min, 170 L/24 hrs) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals to regulate fluid and electrolyte balance (p. 349), blood pressure (p. 447), and acid–base (p. 363) and calcium–phosphate homeostasis (pp. 367 and 368). In addition, the kidneys activate vitamin D and control the synthesis of red blood cells by producing erythropoietin. Strategies to replace each of these important functions are required when managing patients with kidney failure.

Each kidney is approximately 11–14 cm in length in healthy adults; they are located retroperitoneally on either side of the aorta and inferior vena cava between the 12th thoracic and 3rd lumbar vertebrae (Fig. 15.1A). The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

The kidneys have a rich blood supply and receive approximately 20–25% of cardiac output through the renal arteries, which arise from the abdominal aorta. The renal arteries undergo various subdivisions within the kidney, eventually forming interlobular arteries that run through the renal cortex. These eventually give rise to afferent glomerular arterioles that supply the glomeruli. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla in a ‘portal’ circulation (Fig. 15.1B). This highly unusual arrangement of two serial capillary beds reflects the role of the afferent and efferent arterioles in autoregulation of glomerular filtration.

The nephron

Each kidney contains approximately 1 million individual functional units, called nephrons. Each nephron consists of a glomerulus, which is responsible for ultrafiltration of blood, a proximal renal tubule, a loop of Henle, a distal renal tubule and a collecting duct, which together are responsible for selective reabsorption of water and electrolytes that have been filtered at the glomerulus (see Fig. 14.2, p. 350, and Fig. 15.1B). Under normal circumstances, more than 99% of the 170 L of glomerular filtrate that is produced each day is reabsorbed in the tubules. The remainder passes through the collecting ducts of multiple nephrons and drains into the renal pelvis and ureters.

The glomerulus

The glomerulus comprises a tightly packed loop of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. It is surrounded by a cup-shaped extension of the proximal tubule termed Bowman’s capsule, which is composed of epithelial cells. The glomerular capillary endothelial cells contain pores (fenestrae), through which circulating molecules can pass to reach the underlying glomerular basement membrane (GBM), which is formed by fusion of the basement membranes of tubular epithelial and vascular endothelial cells (Fig. 15.1C and D). Glomerular epithelial cells (podocytes) have multiple long foot processes that interdigitate with those of the adjacent epithelial cells, thereby maintaining a selective barrier to filtration (Fig. 15.1E). Mesangial cells lie in the central region of the glomerulus. They have contractile properties similar to those of vascular smooth muscle cells and play a role in regulating glomerular filtration rate.

Under normal circumstances, the glomerulus is impermeable to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are filtered freely. The ability of molecules between 20 and 67 kDa to pass through the GBM is variable and depends on the size (smaller molecules are filtered more easily) and charge (positively charged molecules are filtered more easily). Very little lipid is filtered by the glomerulus.

Filteration pressure at the glomerulus is normally maintained at a constant level, in the face of wide variations in systemic blood pressure and cardiac output, by alterations in muscle tone within the afferent and efferent arterioles and mesangial cells. This is known as autoregulation. Reduced renal perfusion pressure increases local production of prostaglandins that mediate vasodilatation of the afferent arteriole, thereby increasing the intraglomerular pressure (Fig. 15.1D). In addition, renin is released by specialised smooth muscle cells in the juxtaglomerular apparatus in response to reduced perfusion pressure, stimulation of sympathetic nerves or low sodium concentration of fluid in the distal convoluted tubule at the macula densa. Renin cleaves angiotensinogen to release angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) to produce angiotensin II. This restores glomerular perfusion pressure in the short term by causing vasconstriction of the efferent arterioles within the kidney to raise intraglomerular pressure selectively (Fig. 15.1D), and by inducing systemic vasoconstriction to increase blood pressure and thus renal perfusion pressure. In the longer term, angiotensin II increases plasma volume by stimulating aldosterone release, which enhances sodium reabsorption by the renal tubules (see Fig. 18.18, p. 666). Consumption of non-steroidal anti-inflammatory preparations and renin–angiotensin system inhibitors in the context of volume depletion may impair the ability of the kidney to maintain glomerular filtration and exacerbate pre-renal failure (see Fig. 15.19, p. 413).

Renal tubules, loop of Henle and collecting ducts

The proximal renal tubule, loop of Henle, distal renal tubule and collecting ducts are responsible for reabsorption of water, electrolytes and other solutes, as well as regulating acid–base balance, as described in detail on page 350 and in Figure 14.3. They also play a key role in regulating calcium homeostasis by converting 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D (p. 1049). Failure of this process contributes to the pathogenesis of hypocalcaemia and bone disease that occurs in chronic kidney disease (CKD, p. 415). Fibroblast-like cells that lie in the interstitium of the renal cortex are responsible for production of erythropoietin, which in turn is required for production of red blood cells. Erythropoietin synthesis is regulated by oxygen tension; anaemia and hypoxia increase production, whereas polycythaemia and hyperoxia inhibit it.

The ureters and bladder

The ureters drain urine from the renal pelvis (Fig. 15.1A) and deliver it to the bladder, a muscular organ that lies anteriorly in the lower part of the pelvis, just behind the pubic bone. The function of the bladder is to store and then release urine during micturition. The bladder is richly innervated. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia to cause relaxation of the detrusor muscle and contraction of the bladder neck (both via α-adrenoceptors), thereby preventing release of urine from the bladder. The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–4, which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and suppression of detrusor contraction inhibit micturition until it is appropriate. Conversely, parasympathetic nerves arising from S2–4 stimulate detrusor contraction, promoting micturition.

The micturition cycle has a storage (filling) phase and a voiding (micturition) phase. During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. The act of micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

The prostate gland

The prostate gland is situated at the base of the bladder, surrounding the proximal urethra (p. 383). Exocrine glands within the prostate produce fluid, which comprises about 20% of the volume of ejaculated seminal fluid and is rich in zinc and proteolytic enzymes. The remainder of the ejaculate is formed in the seminal vesicles and bulbo-urethral glands, with spermatozoa arising from the prostate.

Smooth muscle fibres within the prostate, which are under sympathetic control, play a role in controlling urine flow through the bulb of the urethra, and also contract at orgasm to move seminal fluid through ejaculatory ducts into the bulb of the urethra (emission). Contraction of the bulbocavernosus muscle (via a spiral muscle reflex) then ejaculates the semen out of the urethra.

The penis

Blood flow into the corpus cavernosum of the penis is controlled by sympathetic nerves from the thoracolumbar plexus, which maintain smooth muscle contraction (p. 383). In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, trapping blood in the lacunar space with consequent elevation of pressure and erection (tumescence) of the penis.

Investigation of renal and urinary tract disease

Glomerular filtration rate

The glomerular filtration rate (GFR) is the sum of the ultrafiltration rates from plasma into the Bowman’s space in each nephron and is a measure of renal excretory function. It is proportionate to body size and the reference value is usually expressed after correction for body surface area as 120±25 mL/min/1.73 m².

The GFR may be measured directly by injecting and measuring the clearance of compounds such as inulin or radio-labelled ethylenediamine-tetra-acetic acid (EDTA), which are completely filtered at the glomerulus and are not secreted or reabsorbed by the renal tubules (Box 15.1). This is not performed routinely, however, and is usually reserved for special circumstances, such as the assessment of renal function in potential live kidney donors. Instead, GFR is usually assessed indirectly in clinical

\*A correction factor of 175 is used for isotope dilution mass spectrometry traceable creatinine measurements. To convert creatinine in mg/dL to \(\mu\text{mol/L}\), multiply by 88.4.
The relationship between serum creatinine and estimated GFR (eGFR) has increased recognition in laboratories of estimated GFR (eGFR) due to the Modification of Diet in Renal Disease (MDRD) equation. Routine reporting by laboratories of eGFR (Fig. 15.2). For this reason, several methods have been developed to estimate GFR from serum creatinine measurements (see Box 15.1) but the most widely used is the Modification of Diet in Renal Disease (MDRD) equation. Routine reporting by laboratories of estimated GFR (eGFR) has increased recognition of moderate kidney damage and encouraged early deployment of protective therapies; however, some limitations remain (Boxes 15.2 and 15.3). In particular, the MDRD formula is based on the serum creatinine value and so is heavily influenced by muscle mass; eGFR may therefore be misleading in individuals whose muscle bulk is outside the normal range for their sex and age. Measurement of other endogenous metabolites, such as cystatin C, may provide a more accurate estimate of GFR in this setting; this test, however, is not yet widely available in routine clinical practice.

Direct measurement of creatinine clearance by collecting a 24-hour urine sample and relating serum creatinine levels to urinary creatinine excretion (see Box 15.1) is now less commonly performed due to the difficulty in obtaining accurate 24-hour urine collections. It may still have a role in assessing renal function in patients at extremes of muscle mass, where the creatinine-based equations perform poorly.

### Urine investigations

Screening for the presence of blood (p. 391), protein (p. 392), glucose, ketones, nitrites and leucocytes, and assessment of urinary pH and osmolality can be achieved by dipstick testing. The presence of leucocytes and nitrites in urine is indicative of urinary tract infection. Urine pH can provide diagnostic information in the assessment of renal tubular acidosis (p. 365).

Urine microscopy (Fig. 15.3) may detect dysmorphic erythrocytes, which suggest the presence of nephritis or red cell casts, indicative of glomerular disease. White cell casts are strongly suggestive of pyelonephritis. Microscopy may also detect the presence of bacteria in those with urinary infection and crystals in patients with renal stone disease. It should be noted that calcium oxalate and urate crystals can sometimes be found in normal urine that has been left to stand, due to crystal formation ex vivo.

1Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Quality Outcomes Initiative 2002. In the 2013 Kidney Disease Outcomes Quality Initiative (K/DOQI) CKD guideline update, the suffixes A1, A2 and A3 are recommended, indicating the presence of albuminuria of <30, 30–300 and >300 mg/24 hrs respectively, in view of the prognostic importance of albuminuria. 2Two GFR values 3 months apart are required to assign a stage. All GFR values are in mL/min/1.73 m². 3Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies. 4From Hill NR, Fatoba ST, Oke JL et al. Global prevalence of chronic kidney disease – a systematic review and meta-analysis. PLoS One 2016; 11:e0158765. 5For further information, see page 415.

Urine collection over a 24-hour period may be performed to measure excretion of solutes, such as calcium, oxalate and urate, in patients with recurrent renal stone disease (p. 431). Proteinuria can also be measured on 24-hour collections but is usually now quantified by protein/creatinine ratio on spot urine samples.

Other dynamic tests of tubular function, including concentrating ability (p. 431), ability to excrete a water load (p. 357) and ability to excrete acid (p. 415), and calculation of fractional calcium, phosphate or sodium excretion, are valuable in some circumstances but are usually performed in very specific contexts.

Fig. 15.3 Urine microscopy. A Erythrocytes due to bleeding from lower in the urinary tract (×400). B Dysmorphic erythrocytes due to glomerular inflammation (×400). C Hyaline casts in normal urine. D Erythrocytes and a red cell cast in glomerulonephritis (×100). Panels A–C are phase contrast images; D is a bright field image. (A, B) Courtesy of Dr G.M. Iadorola and Dr F. Quarello, B. Bosco Hospital, Turin (from www.sin-italia.org/imago/sediment/sed.htm).

The fractional excretion of these ions can be calculated by the general formula: 100 × (urine concentration of analyte × serum creatinine) / (serum concentration of analyte × urinary creatinine). Calculation of fractional excretion of sodium (FENa) can help in the setting of acute kidney injury (AKI) to differentiate volume depletion, when the tubules are avidly conserving sodium (FENa typically <1.0%), from acute tubular necrosis, when the tubules are damaged and are less able to conserve sodium (FENa typically >1.0%). In clinical practice this is seldom required.

Blood tests

| Haematology |
A normochromic normocytic anaemia is common in CKD and is due in part to deficiency of erythropoietin and bone marrow suppression secondary to toxins retained in CKD. Other causes of anaemia include iron deficiency from urinary tract bleeding, and haemolytic anaemia secondary to disorders such as haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Other abnormalities may be observed that reflect underlying disease processes, such as neutrophilia and raised erythrocyte sedimentation rate (ESR) in vasculitis or sepsis, and lymphopenia and raised ESR in systemic lupus erythematosus (SLE). Fragmented red cells on blood film and low platelets may be observed in thrombotic microangiopathies such as HUS/TTP and malignant hypertension. Pancytopenia may occur in SLE or bone marrow suppression due to myeloma.

Biochemistry

Abnormalities of routine biochemistry are common in renal disease. Serum levels of creatinine may be raised, reflecting reduced GFR (see above), as may serum potassium. Serum levels of urea are often increased in kidney disease but this analyte has limited value as a measure of GFR since levels increase with protein intake, following gastrointestinal haemorrhage and in catabolic states. Conversely, urea levels may be reduced in patients with chronic liver disease or anorexia and in malnourished patients, independently of changes in renal function. In the absence of the other causes mentioned above, an elevated urea:creatinine
ratio is indicative of volume depletion and pre-renal failure. Serum calcium tends to be reduced and phosphate increased in CKD, in association with high parathyroid hormone (PTH) levels caused by reduced production of 1,25-dihydroxyvitamin D (1,25(OH)2D) by the kidney (secondary hyperparathyroidism). In some patients, this may be accompanied by raised serum alkaline phosphatase levels, which are indicative of renal osteodystrophy. Serum bicarbonate may be low in renal failure and in renal tubular acidosis. Serum albumin may be low in liver disease, as a negative acute phase response or due to malnutrition/malabsorption, but if it is a new finding it should prompt urinalysis to exclude nephrotic syndrome. Other biochemical abnormalities may be observed that reflect underlying disease processes, such as raised glucose and HbA1c levels in diabetes mellitus (p. 729) and raised levels of C-reactive protein (CRP) in sepsis and vasculitis.

### Immunology

Antinuclear antibodies, antibodies to extractable nuclear antigens and anti-double-stranded DNA antibodies may be detected in patients with renal disease secondary to SLE (p. 1034). Antineutrophil cytoplasmic antibodies (ANCA) may be detected in patients with glomerulonephritis secondary to systemic vasculitis (p. 1040), as may antibodies to GBM in patients with Goodpasture’s syndrome (p. 401), and low levels of complement may be observed in a number of kidney diseases (see Box 15.17, p. 401).

### Imaging

#### Ultrasound

Renal ultrasound is a valuable non-invasive technique that may be performed to assess renal size and to investigate patients who are suspected of having obstruction of the urinary tract (Fig. 15.4), renal tumours, cysts or stones. Ultrasound can also be used to provide images of the prostate gland and bladder, and to estimate the completeness of emptying in patients with suspected bladder outflow obstruction. In addition, it can reveal other abdominal, pelvic and retroperitoneal pathology. Ultrasonography may show increased signal in the renal cortex with loss of distinction between cortex and medulla, which is characteristic of CKD. Doppler imaging can be used to study blood flow in extrarenal and larger intrarenal vessels, and to assess the resistivity index (peak systolic velocity – end-diastolic velocity/peak systolic velocity in the intrarenal arteries), which may be elevated (>0.7) in various diseases, including acute tubular necrosis and rejection of a renal transplant. However, renal ultrasound is operator-dependent and the results are often less clear in obese patients.

### Computed tomography

Computed tomography urography (CTU) is used to evaluate cysts and mass lesions in the kidney or filling defects within the collecting systems. It usually entails an initial scan without contrast medium, and subsequent scans following injection of contrast to obtain a nephrogram image and images during the excretory phases. CTU has largely replaced the previous gold-standard investigation of intravenous urography (IVU) for investigation of the upper urinary tract, having the advantage of providing complete staging information and details of surrounding organs. Contrast enhancement is particularly useful for characterising mass lesions within the kidney and differentiating benign from malignant lesions (see Fig. 15.32A, p. 435). CT without contrast gives clear definition of retroperitoneal anatomy regardless of obesity and is superior to ultrasound in this respect. Non-contrast CT of kidneys, ureters and bladder (CTKUB) is the method of choice for demonstrating stones within the kidney or ureter (see Fig. 15.29, p. 432). For investigation of patients with renal trauma, a triple-phase CT scan with a delayed phase, to assess the integrity of the collecting system, is performed. Drawbacks of contrast-enhanced CT scans include the fact that relatively large doses of contrast medium are required, which can cause renal dysfunction, and that the radiation dose is significant (Box 15.4).

### Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers excellent resolution and gives good distinction between different tissue types (see Fig. 15.15, p. 406). It is very useful for local staging of prostate, bladder and penile cancers. Magnetic resonance angiography (MRA) provides an alternative to CT for imaging renal vessels but involves administration of gadolinium-based contrast media, which may carry risks for patients with impaired renal function (Box 15.4). Whilst MRI provides good images of the main renal vessels, stenosis of small branch arteries may be missed.

#### Renal arteriography

Renal arteriography involves taking X-rays following an injection of contrast medium directly into the renal artery. The main indication is to investigate renal artery stenosis (p. 406) or haemorrhage following renal trauma. Renal angiography can often be combined with therapeutic balloon dilatation or stenting of the renal artery. It can be used to occlude bleeding vessels and arteriovenous fistulae by the insertion of thin platinum wires (coils). These curl up within the vessel and promote thrombosis, thereby securing haemostasis.

![Fig. 15.4 Renal ultrasound.](image)
Formal measurements of GFR can be made by radionuclide studies following the injection of diethylenetriamine penta-acetic acid (99mTc-DPTA).

**Static radionuclide studies** are performed with dimercaptosuccinic acid labelled with technetium (99mTc-DMSA), which is taken up by proximal tubular cells. Following intravenous injection, images of the renal cortex are obtained that show the shape, size and relative function of each kidney (Fig. 15.6). This is a sensitive method for demonstrating cortical scarring in reflux nephropathy and a way of assessing the individual function of each kidney.

**Radionuclide bone scanning** following the injection of methylene diphosphonate (99mTc-MDP) is indicated to assess the presence and extent of bone metastases in men with advanced prostate cancer (p. 438).

**Pyelography**

Pyelography involves direct injection of contrast medium into the collecting system from above (antegrade) or below (retrograde). It offers the best views of the collecting system and upper tract, and is often used to identify the cause of urinary tract obstruction (p. 391). Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. In addition to visualising the cause of obstruction, percutaneous nephrostomy drainage can be established and often stents can be passed through any obstruction. Retrograde pyelography can be performed by inserting a ureteric catheter into the ureteric orifice at cystoscopy (Fig. 15.5) and again a stent can be inserted to bypass any obstruction.

**Radionuclide studies**

These are functional studies requiring the injection of gamma ray-emitting radiopharmaceuticals that are taken up and excreted by the kidney, a process that can be monitored by an external gamma camera.

Dynamic radionuclide studies are performed with mercaptoacetyltriglycine labelled with technetium (99mTc-MAG3), which is filtered by the glomerulus and excreted into the urine. Imaging following 99mTc-MAG3 injection can provide valuable information about the perfusion of each kidney but is not a reliable method for identifying renal artery stenosis. In patients with significant obstruction of the outflow tract, 99mTc-MAG3 persists in the renal pelvis and a loop diuretic fails to accelerate its disappearance. This can be useful in determining the functional significance of an equivocally obstructed collecting system without undertaking pyelography.

**Fig. 15.5 Retrograde pyelography.** The best views of the normal collecting system are shown by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. The anemone-like calyces are sharp-edged and normal. Courtesy of Dr A.P. Bayliss and Dr P. Thorpe, Aberdeen Royal Infirmary.

**Fig. 15.6 DMSA radionuclide scan.** A posterior view is shown of a normal left kidney and a small right kidney (with evidence of cortical scarring at upper and lower poles) that contributes only 39% of total renal function.
is markedly reduced, such as occurs in diabetic ketoacidosis

in such cases until the pre-renal insult becomes severe and GFR
dysfunction may, however, produce normal or high urine volumes

conserve salt and water. A high solute load or associated tubular
and tubular homeostatic mechanisms increase reabsorption to
urine production, as in pre-renal AKI, when GFR is reduced

urine volume alone is a poor indicator of the severity of kidney
may still be normal if tubular reabsorption is also reduced; hence
reabsorbed by the renal tubules. When GFR is low, urine volumes

the amount of fluid that is filtered at the glomerulus and that

less than 100 mL of urine is passed per day.

Oliguria is defined as being present when less than 400 mL of
urine is passed per day, whereas anuria is deemed to exist when
less than 100 mL of urine is passed per day.

The volume of urine produced represents a balance between
the amount of fluid that is filtered at the glomerulus and that
reabsorbed by the renal tubules. When GFR is low, urine volumes
may still be normal if tubular reabsorption is also reduced; hence
urine volume alone is a poor indicator of the severity of kidney
disease. Oliguria and anuria may be caused by a reduction in
urine production, as in pre-renal AKI, when GFR is reduced
and tubular homeostatic mechanisms increase reabsorption to
conservate salt and water. A high solute load or associated tubular
dysfunction may, however, produce normal or high urine volumes
in such cases until the pre-renal insult becomes severe and GFR
is markedly reduced, such as occurs in diabetic ketoacidosis

with marked glycosuria. Urine volumes are variable in AKI due
to intrinsic renal disease, but a rapid decline in urine volume
may be observed. Anuria should prompt a differential including
complete urinary obstruction, severe vascular compromise or
rapidly progressive glomerulonephritis (Box 15.6).

Obstruction of the renal tract can produce oliguria and anuria,
but to do so, obstruction must be complete and occur distal to
the bladder neck, be bilateral, or be unilateral on the side of a
single functioning kidney. Unilateral ureteric obstruction may not
lead to any noticeable reduction in urine output. The presence
of pain that is exacerbated by a fluid load suggests an acute
obstruction of the renal tract, and its characteristics may be of
value in reaching a diagnosis. Obstruction at the bladder neck
is associated with lower midline abdominal discomfort, whereas
ureteric obstruction typically presents as loin pain radiating to
the groin and at the level of the renal pelvis may present as
flank pain. Chronic obstruction rarely produces pain but may
give rise to a dull ache. Urethral strictures should be considered
as a possible cause, especially in patients with a history of
instrumentation of the renal tract.

The presence of bladder enlargement in a middle-aged or
elderly man suggests benign or malignant enlargement of the
prostate gland as a potential cause of oliguria or anuria (pp.
437 and 438). It is important to note that many cases of acute urinary
retention are observed after general anaesthesia, particularly in
patients with pre-existing prostatic enlargement. Partial obstruction
can be associated with a normal or even high urine volume due to
chronic tubular injury, which causes loss of tubular concentrating
ability. Management of oliguria and anuria should be directed at
the underlying cause and is outlined later in the chapter (p. 413).

**Presenting problems in renal and urinary tract disease**

**Oliguria/anuria**

Healthy individuals may have occasional red blood cells in
the urine (up to 12 500 cells/mL), but the presence of visible
(macroscopic) haematuria or non-visible haematuria (microscopic,
only detectable on dipstic testing) is indicative of significant
bleeding from somewhere in the urinary tract (Fig. 15.7). Once
infection, menstruation and causes of a positive urinary dipstick
test for red cells (haemoglobinuria/myoglobinuria) have

**Renal biopsy**

Renal biopsy is used to establish the diagnosis and severity
of renal disease in order to judge the prognosis and need for
treatment (Box 15.5). The procedure is performed transcutaneously
under local anaesthetic with ultrasound or contrast radiography
guidance to ensure accurate needle placement into a renal pole.
Light microscopy, electron microscopy and immunohistological
assessment of the specimen may all be required.

**15.5 Renal biopsy**

**Indications**

- Acute kidney injury and chronic kidney disease of uncertain
  aetiology
- Nephrotic syndrome or glomerular proteinuria (protein:creatinine
  ratio > 100 mg/mol) in adults
- Nephrotic syndrome in children that has atypical features or is not
  responding to treatment
- Nephritic syndrome
- Renal transplant dysfunction
- Rarely performed for isolated haematuria or isolated low-grade
  proteinuria in the absence of impaired renal function or evidence of a
  multisystem disorder

**Contraindications**

- Disordered coagulation or thrombocytopenia. Aspirin and other
  antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys < 60% predicted size
- Solitary kidney* (except transplants)

**Complications**

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and
  obstruction
- Bleeding around the kidney, occasionally massive and requiring
  angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

*Relative contraindication.

**15.6 Causes of anuria (~100 mL urine output per day)**

**Condition Examples**

- **Urinary obstruction (complete)**
  - Urinary retention due to prostatic enlargement, urethral stenosis, bladder tumour
  - Bilateral ureteric obstruction due to retroperitoneal fibrosis, cancer, radiation injury
  - Bilateral renal stones (usually staghorn calculi)
  - Massive crystalluria obstruction of tubules (rare)

- **Lack of renal perfusion (bilateral)**
  - Aortic dissection involving renal arteries
  - Severe acute tubular necrosis
  - Severe functional hypoperfusion (cardiorenal, hepatorenal)

- **Rapidly progressive glomerulonephritis**
  - Anti-glomerular basement membrane disease
  - Severe antineutrophil cytoplasmic antibody (ANCA) vasculitis (100% glomerular crescents on biopsy)
be excluded (Box 15.7), both visible and persistent non-visible haematuria require investigation, as they may be caused by malignancy or indicate glomerulonephritis.

Visible haematuria is most likely to be caused by tumour, which can affect any part of the urogenital tract (Fig. 15.7), and patients with visible haematuria must therefore be referred to urology for imaging (ultrasound or CT scan) and cystoscopy. In younger patients, an underlying tumour is much less likely, and if a glomerular cause is not suspected (see below), it may be appropriate to manage them by periodic observation in primary care, although occasionally these individuals develop significant overt renal disease during follow-up.

Glomerular bleeding occurs when inflammatory, destructive or degenerative processes disrupt the GBM, permitting passage of red blood cells into the urine. A characteristic feature of glomerular bleeding is an ‘active urinary sediment’ (the presence of dysmorphic red blood cells or red cell casts on microscopy); this is not always present, however. Patients with visible and non-visible haematuria should also be assessed for hypertension, proteinuria, reduced/declining renal function, family history of renal disease or features of systemic disease (Fig. 15.8). The presence of any of these features raises the possibility of intrinsic renal pathology and warrants referral to nephrology for further investigation, including consideration of renal biopsy.

### Nephritic syndrome

The nephritic syndrome is characterised by the presence of haematuria in association with hypertension, oliguria, fluid retention and reduced/declining renal function. Many patients with glomerulonephritis, particularly those with milder disease, do not exhibit all of these features; their combined presence, however, is typical of a rapidly progressive glomerulonephritis and warrants urgent investigation. In many cases, investigation will include a renal biopsy to confirm diagnosis and guide management, but less invasive investigations may also be useful (Box 15.8).

### Proteinuria

While very small amounts of high-molecular-weight proteins and moderate amounts of low-molecular-weight proteins pass
Presenting problems in renal and urinary tract disease

• 393

The presence of larger amounts of protein is usually indicative of significant renal disease. Proteinuria is usually asymptomatic and is often picked up by urinalysis, although large amounts of protein may make the urine frothy. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in people with urinary tract infection.

Through the healthy GBM, these proteins normally are completely reabsorbed by receptors on tubular cells. Hence, in healthy individuals, less than 150 mg of protein is excreted in the urine each day, much of which is derived from tubular cells. This includes Tamm–Horsfall protein (uromodulin), encoded by the UMOD gene that has recently been linked to tubulo-interstitial nephritis (see Box 15.20, p. 405). The presence of larger amounts of protein is usually indicative of significant renal disease.

Proteinuria is usually asymptomatic and is often picked up by urinalysis, although large amounts of protein may make the urine frothy. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in people with urinary tract infection.

Fig. 15.8 Investigation of haematuria. *Symptomatic: lower urinary tract voiding symptoms such as hesitancy, frequency, urgency and dysuria. (ACR = albumin:creatinine ratio; BP = blood pressure; CT = computed tomography; eGFR = estimated glomerular filtration rate; NVH = non-visible haematuria; UTI = urinary tract infection)

Fig. 15.9 Nephritic and nephrotic syndrome. At one extreme, specific injury to podocytes causes proteinuria and nephrotic syndrome. The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the glomerular basement membrane (GBM) and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome. The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells, and influx of inflammatory cells leading to crescent formation (arrows) in response to severe post-infectious glomerulonephritis. (FSGS = focal and segmental glomerulosclerosis; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)

\(^1\)Urinary albumin (mg/L)/urine creatinine (mmol/L), \(^2\)Urine protein (mg/L)/urine creatinine (mmol/L). (If urine creatinine is measured in mg/dL, reference values for PCR and ACR can be derived by dividing by 11.31.) \(^3\)Dipstick results are affected by urine concentration and are occasionally weakly positive on normal samples.

Overt (dipstick-positive) proteinuria

Urinary dipstick testing is a valuable screening tool for the detection of proteinuria; it is only semi-quantitative, however, as it is highly dependent on the concentration of the urine. Typically, standard dipsticks test positive for protein once the urinary protein exceeds approximately 0.5 g/24 hrs; however, trace to 1+ on dipstick may be observed in very concentrated urine from individuals with no evidence of renal pathology. Hence all patients with persistent proteinuria on dipstick should have the amount of protein quantified to guide further investigations (Fig. 15.10). When more than 1 g of protein per day is being excreted, glomerular disease is likely and this is an indication for renal biopsy. Since quantification by 24-hour urine collection is often inaccurate, the protein:creatinine ratio (PCR) in a spot sample of urine is preferred. This makes an allowance for the variable degree of urinary dilution and can be used to extrapolate to 24-hour values (Box 15.9). Changes in PCR also give valuable information about the progression of renal disease and response to therapy in CKD.
Nephrotic syndrome

Nephrotic syndrome is characterised by very heavy proteinuria (>3.5 g/24 hrs), hypoalbuminaemia and oedema (see below). Blood volume may be normal, reduced or increased. Renal sodium retention is an early and universal feature; the mechanisms of this are shown in Figure 14.5 (p. 354). The diseases that cause nephrotic syndrome all affect the glomerulus (see Fig. 15.9), either directly, by damaging podocytes, or indirectly, by causing scarring or deposition of exogenous material such as amyloid into the glomerulus.

Investigation of nephrotic syndrome usually involves renal biopsy, although non-invasive tests may also be helpful in suggesting the underlying cause (Box 15.10). In children, minimal change disease is by far the most common cause of nephrotic syndrome and therefore renal biopsy is not usually required unless the patient fails to respond to high-dose glucocorticoid therapy. Similarly, most patients with diabetes presenting with nephrotic syndrome will have diabetic nephropathy, and so renal biopsy is usually not performed unless the course of the disease is atypical (rapidly increasing proteinuria or rapid decline in renal function; p. 757).

Management of nephrotic syndrome should be directed at the underlying cause. In addition, nephrotic syndrome is associated with a number of complications (Box 15.11), which may require supportive management unless the nephrosis is expected to resolve rapidly, such as in glucocorticoid-responsive minimal change disease.

Oedema

Oedema is caused by an excessive accumulation of fluid within the interstitial space. Clinically, this can be detected by persistence of an indentation in tissue following pressure on the affected area (pitting oedema). Pitting oedema tends to accumulate in the ankles during the day and improves overnight as the interstitial fluid is reabsorbed. Non-pitting oedema is typical of lymphatic obstruction and may also occur as the result of excess matrix deposition in tissues: for example, in hypothyroidism (p. 639) or systemic sclerosis (p. 1037).

Clinical assessment

Dependent areas, such as the ankles and lower legs, are typically affected first but oedema can be restricted to the sacrum in bed-bound patients. With increasing severity, oedema spreads to affect the upper parts of the legs, the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common but frank pulmonary oedema is rare. Facial oedema on waking is common. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased

*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). In occasional patients with hypovolaemia, intravenous salt-poor albumin infusions may help to establish a diuresis, although efficacy is controversial. Over-diuresis risks secondary impairment of renal function through hypovolaemia.

at risk of developing CKD and current recommendations are 

that hypertensive patients should have renal function checked 

annually. Control of hypertension is very important in patients with 

renal impairment because of its close relationship with further 

decline of renal function (p. 420) and because of the exaggerated 

cardiovascular risk associated with CKD. Pathophysiology and 

management are discussed on pages 509 and 510.

Investigations

Oedema may be due to a number of causes (Box 15.12), which are usually apparent from the history and examination of the cardiovascular system and abdomen. Blood should be taken for measurement of urea and electrolytes, liver function and serum albumin, and the urine tested for protein. Further imaging of the liver, heart or kidneys may be indicated, based on history and clinical examination. Where ascites or pleural effusions occur in isolation, aspiration of fluid with measurement of protein and glucose, and microscopy for cells, will usually help to clarify the diagnosis in differentiating a transudate (typical of oedema) from an exudate (more suggestive of local pathology, p. 564).

Management

Mild oedema usually responds to elevation of the legs, compression stockings, or a thiazide or a low dose of a loop diuretic, such as furosemide or bumetanide. In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance. Restriction of sodium intake and fluid intake may be required. Diuretics are not helpful in the treatment of oedema caused by venous or lymphatic obstruction or by increased capillary permeability. Specific causes of oedema, such as venous thrombosis, should be treated.

Hypertension

Hypertension is a very common feature of renal disease. Additionally, the presence of hypertension identifies a population

Loin pain

Loin pain is often caused by musculoskeletal disease but can be a manifestation of renal tract disease; in the latter case, it may arise from renal stones, ureteric stones, renal tumours, acute pyelonephritis and urinary tract obstruction. Acute loin pain radiating anteriorly and often to the groin is termed renal colic. When combined with haematuria, this is typical of ureteric obstruction due to calculi (p. 431). Precipitation of loin pain by a large fluid intake (Dietl’s crisis) suggests upper urinary tract obstruction caused by a congenital abnormality of the pelvi-ureteric junction (p. 433).

Dysuria

Dysuria refers to painful urination, often described as burning, scalding or stinging, and commonly accompanied by suprapubic pain. It is often associated with frequency of micturition and a feeling of incomplete emptying of the bladder. By far the most common cause is urinary tract infection, as described on page 426. Other diagnoses that need to be considered in patients with dysuria include sexually transmitted infections (p. 329) and bladder stones (p. 431).

Frequency

Frequency describes daytime micturition more often than a patient would expect. It may be a consequence of polyuria, when urine volume is normal or high, but is also found in patients with dysuria and prostatic diseases, when the urine volume is normal.

Polyuria

Polyuria is defined as a urine volume in excess of 3 L/24 hrs. Various underlying conditions, both renal and extrarenal, may be responsible, as outlined in Box 15.13.

Investigation of polyuria includes measurement of urea, creatinine and electrolytes, glucose, calcium and albumin. A 24-hour urine collection may be helpful to confirm the severity of polyuria. The presence of nocturnal polyuria suggests a
pathological cause. Investigation and management of suspected diabetes insipidus are described on page 688.

Nocturia

Nocturia is defined as waking up at night to void urine. It may be a consequence of polyuria but may also result from increased fluid intake or diuretic use in the late evening (including caffeine). Nocturia also occurs in CKD, and in prostatic enlargement when it is associated with poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 437). Nocturia may also occur due to sleep disturbance without any functional abnormalities of the urinary tract.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (see Box 15.54, p. 436). The pathophysiology, investigation and management of urinary incontinence are discussed in detail later in the chapter (p. 436).

Glomerular diseases

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. Most patients with glomerular disease do not present acutely and are asymptomatic until abnormalities are detected on routine screening of blood or urine samples.

There are many causes of glomerular damage, including immunological injury, inherited diseases such as Alport’s syndrome (p. 403), metabolic diseases such as diabetes mellitus (p. 757), and deposition of abnormal proteins such as amyloid in the glomeruli (p. 81). The glomerular cell types that may be the target of injury are shown in Figure 15.11. Proteinuria is in the glomeruli (p. 81). The glomerular cell types that may be change nephropathy) are not associated with inflammation. Glomerular disease, even though some of these (e.g. minimal

While glomerulonephritis literally means ‘inflammation of glomeruli’, the term is often used more broadly to describe all types of glomerular disease, even though some of these (e.g. minimal change nephropathy) are not associated with inflammation.

Most types of glomerulonephritis are immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis and testing for circulating or glomerular deposition of antibodies may aid diagnosis (see Fig. 15.11 and Boxes 15.8 and 15.10). In small-vessel vasculitis, no glomerular antibody deposition is observed (pauci-immune), but the antibodies may be indirectly pathogenic by activating neutrophils to promote endothelial injury (Fig. 15.11).

Glomerulonephritis is generally classified in terms of the histopathological appearances, as summarised in Box 15.15 and Figure 15.12. Many non-specialists find the terminology used in describing glomerulonephritis to be confusing; some definitions are provided in Box 15.16. It is important to stress that the histological appearance rarely confirms a specific renal disease but rather suggests a limited range of diagnoses, which may be confirmed by further investigation. Conversely, some diseases, such as lupus, are associated with more than one histological pattern of injury. The most common histological subtypes may be categorised according to their typical clinical presentation, as discussed below. Genetic disorders associated with glomerular disease are described later (p. 403).

Post-infectious glomerulonephritis

Fig. 15.11 Glomerulonephritis associated with antibody production. Antibodies and antigen–antibody (immune) complexes may target or be deposited in specific components of the glomerulus, resulting in different patterns of histological injury and clinical presentation. Testing for antibody deposition in the glomerulus by immunofluorescence (IF) on renal biopsy tissue or for antibodies in the serum may aid diagnosis. Diagnostic tests are shown in italics. (ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; dsDNA = double-stranded DNA; GBM = glomerular basement membrane; IgA = immunoglobulin A; SLE = systemic lupus erythematosus)
Minimal change nephropathy

Minimal change disease occurs at all ages but accounts for most cases of nephrotic syndrome (see Box 15.15) in children and about one-quarter of adult cases. It is caused by reversible dysfunction of podocytes. On light microscopy, the glomeruli appear normal (Fig. 15.12A), but fusion of podocyte foot processes is observed on electron microscopy. The presentation is with nephrotic syndrome, which typically is severe; it remits...

**Diffuse proliferative glomerulonephritis**

| Diffuse proliferation of endothelial and mesangial cells | Subendothelial and subepithelial | Immune complex-mediated (e.g. to streptococcal infection with presumed cross-reactive epitopes) | Post-streptococcal Concurrent infection with staphylococci, endocarditis | Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria. Usually resolves spontaneously |
| Infiltration by neutrophils and macrophages ± crescent formation | | | | |

**Anti-glomerular basement membrane disease**

| Usually crescentic nephritis | Linear IgG along GBM | Autoantibodies to α3 chain of type IV collagen in GBM | HLA-DR15 (previously known as DR2) | Associated with lung haemorrhage but renal or lung disease may occur alone. Treat with glucocorticoids, cyclophosphamide and plasma exchange |

---

1. Systemic lupus erythematosus can cause almost any histological injury pattern, most commonly membranous nephropathy or diffuse proliferative glomerulonephritis.
2. In addition to the association with infection and anti-GBM disease, a diffuse proliferative glomerulonephritis picture may also be seen with lupus and occasionally IgA nephropathy.
3. Infection may also present with mesangio-proliferative glomerulonephritis and membranous nephropathy (HIV).

(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; APOL1 = apolipoprotein L1; GBM = glomerular basement membrane; HLA = human leucocyte antigen; IgA = immunoglobulin A; NSAIDs = non-steroidal anti-inflammatory drugs)

---

**Fig. 15.12** Histopathology of glomerular disease. (A–E) Light microscopy (A) A normal glomerulus. Note the open capillary loops and thinness of their walls. (B) Focal segmental glomerulosclerosis (GS). The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. (C) Focal necrotising glomerulonephritis (GN). A portion of the glomerulus (N = focal necrotising lesion) is replaced by bright pink material with some ‘nuclear dust’. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see E). (D) Membranous glomerulonephritis. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. (E) Crescentic glomerulonephritis. The lower part of Bowman’s space is occupied by a semicircular formation (‘crescent’, Cr) of large pale cells, compressing the glomerular tuft. This is seen in aggressive inflammatory glomerulonephritis. Antibody deposition in the glomerulus. (F, H) Direct immunofluorescence. (G) Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous GN. (E) Immunoglobulin A (IgA) deposits in the mesangium, as seen in IgA nephropathy. (H) Ribbon-like linear deposits of anti-GBM antibodies along the glomerular basement membrane in Goodpasture’s disease. The glomerular structure is well preserved in all of these examples. (A, C, D, E) Courtesy of Dr J.G. Simpson, Aberdeen Royal Infirmary. (F, G, H) Courtesy of Dr R. Herriot.
with high-dose glucocorticoid therapy (1 mg/kg prednisolone for 6 weeks), though the response to therapy is often less satisfactory in older patients. Some patients who respond incompletely (glucocorticoid-resistant) or relapse frequently need maintenance glucocorticoids (glucocorticoid dependence), cytotoxic therapy or other agents. Glucocorticoid resistance in children warrants a biopsy to exclude an alternative diagnosis, but if minimal change is confirmed, a genetic cause should be considered (p. 403). Minimal change disease typically does not progress to CKD but can present with problems related to the nephrotic syndrome (see Box 15.11) and complications of treatment.

**Focal segmental glomerulosclerosis**

Primary focal segmental glomerulosclerosis (FSGS) (Fig. 15.12B) can occur in all age groups but is particularly common in people of West African descent, who, compared with other ethnicities, have a much higher carriage rate of an apolipoprotein L1 (APOL1) gene variant that is associated with increased risk of FSGS. Histological analysis shows sclerosis initially limited to segments of the glomeruli, which may also show positive staining for deposits of C3 and IgM on immunofluorescence. Since FSGS is a focal process, abnormal glomeruli may not be seen on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy. In most cases the underlying cause is unknown (primary FSGS) and these patients typically present with abrupt onset of severe nephrotic syndrome. Primary FSGS may respond to high-dose glucocorticoid therapy (0.5–2.0 mg/kg/day) but the response is rarely as rapid or complete as for minimal change disease. Immunosuppressive drugs, such as ciclosporin, cyclophosphamide and mycophenolate mofetil, have also been used but their efficacy is uncertain. Progression to CKD is common in patients who do not respond to glucocorticoids and the disease frequently recurs after renal transplantation.

FSGS may also be secondary to other diseases such as human immunodeficiency virus (HIV) renal disease (particularly in African Americans), morbid obesity or chronic hypertension. In addition, it may reflect scarring from previous focal glomerular injury resulting from HUS, cholesterol embolism or vasculitis. Patients with secondary FSGS typically present with more modest proteinuria than those with primary disease and rarely exhibit full-blown nephrotic syndrome. Management of secondary FSGS is focused on treating the underlying cause and reducing proteinuria by inhibiting the renin–angiotensin system (p. 417).

**Membranous nephropathy**

Membranous nephropathy is the most common cause of nephrotic syndrome in Caucasian adults. It is caused by antibodies (usually autoantibodies) directed at antigen(s) expressed on the surface of podocytes, including the M-type phospholipase A2 receptor 1. While most cases are idiopathic, a proportion are associated with other causes, such as heavy metal poisoning, drugs, infections, lupus and tumours (see Box 15.15 and Fig. 15.12D and F). Approximately one-third of patients with idiopathic membranous nephropathy undergo spontaneous remission, one-third remain in a nephrotic state, and one-third develop progressive CKD. High doses of glucocorticoids and cyclophosphamide may improve both the nephrotic syndrome and the long-term prognosis. However, because of the toxicity of these regimens, many nephrologists reserve such treatment for those with severe nephrotic syndrome or deteriorating renal function. Treatment of secondary membranous nephropathy is directed at the underlying cause.

**Diseases typically presenting with mild nephritic syndrome**

Patients with mild glomerulonephritis typically present with non-visible haematuria and modest proteinuria, and their renal disease tends to follow a slowly progressive course. IgA nephropathy and mesangiocapillary glomerulonephritis (MCGN) typically fall in this category. Their presentation is highly variable, however; IgA nephropathy occasionally presents with rapidly progressive glomerulonephritis while MCGN may present with nephrotic syndrome. Other diseases that present with haematuria, modest proteinuria and slow progression include Alport’s syndrome (p. 403).

**IgA nephropathy**

This is one of the most common types of glomerulonephritis and can present in many ways. Haematuria is the earliest sign and non-visible haematuria is almost universal, while hypertension is also very common. These are often detected during routine screening: for example, at occupational medical examinations. Proteinuria can also occur but is usually a later feature. In many cases, there is slowly progressive loss of renal function leading to end-stage renal disease (ESRD). A particular hallmark of IgA nephropathy in young adults is the occurrence of acute self-limiting exacerbations, often with visible haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to nephritis is short: a few days or less. Asymptomatic presentations dominate in older adults, with non-visible haematuria, hypertension and reduction in GFR. Occasionally, IgA nephropathy progresses rapidly in association with crescent formation on biopsy. Management is largely directed towards the control of blood pressure, with renin–angiotensin system inhibitors preferable in those with proteinuria. There is some evidence for additional benefit from several months of high-dose glucocorticoid treatment in those at high-risk of progressive disease (see Box 15.14), but no strong evidence for other immunosuppressive agents. A role for other therapies, such as fish oil, remains uncertain.
Henoch–Schönlein purpura

This condition most commonly occurs in children but can also be observed in adults. It is a systemic vasculitis that often arises in response to an infectious trigger. It presents with a tetrad of features:

- a characteristic petechial rash typically affecting buttocks and lower legs
- abdominal pain due to vasculitis involving the gastrointestinal tract
- arthralgia
- renal disease characterised by visible or non-visible haematuria, with or without proteinuria.

Renal biopsy shows mesangial IgA deposition and appearances that are indistinguishable from acute IgA nephropathy (Fig. 15.12G). Treatment is supportive in nature; in most patients, the prognosis is good, with spontaneous resolution, though relapses are common. Some patients, particularly adults and those with severe or persistent proteinuria, progress to develop ESRD.

Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis (MCGN), also known as membranoproliferative glomerulonephritis, is a pattern of injury seen on renal biopsy that is characterised by an increase in mesangial cellularity with thickening of glomerular capillary walls. The typical presentation is with proteinuria and haematuria. Several underlying causes have been identified, as summarised in Box 15.15. It can be classified into two main subtypes. The first is characterised by deposition of immunoglobulins within the glomeruli. This subtype is associated with chronic infections, autoimmune diseases and monoclonal gammapathy. The second is characterised by deposition of complement in the glomeruli and is associated with inherited or acquired abnormalities in the complement pathway. This category comprises ‘dense deposit disease’, which is typified by electron-dense deposits within the GBM, and C3 glomerulonephritis that shows deposits similar to immunoglobulin-type MCGN.

Treatment of MCGN associated with immunoglobulin deposits consists of the identification and treatment of the underlying disease, if possible, and the use of immunosuppressive drugs such as mycophenolate mofetil or cyclophosphamide. There are few specific treatments for MCGN associated with complement dysregulation, although eculizumab, the anti-C5 inhibitor that prevents formation of the membrane attack complex, has shown promise.

Diseases typically presenting with rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is characterised by rapid loss of renal function over days to weeks, usually in association with hypertension and oedema. Non-visible haematuria is almost always present with variable amounts of proteinuria, while characteristic red cell casts and dysmorphic red cells may be observed on urine microscopy (see Fig. 15.3). Renal biopsy typically shows crescentic lesions (see Fig. 15.12E), often associated with necrotising lesions within the glomerulus (Fig. 15.12C), particularly in small-vessel vasculitides.

This pattern of presentation is typical of post-infectious glomerulonephritis, anti-GBM disease and small-vessel vasculitides (p. 1040). It can also be observed in SLE (p. 1034) and occasionally in IgA and other nephropathies (see Fig. 15.9).

Anti-glomerular basement membrane disease

Anti-GBM disease is a rare autoimmune disease in which antibodies develop against the α3 chain of type 4 collagen GBM. Expression of the α3 chain is largely restricted to the basement membranes of glomeruli and lungs, and hence the disease may present with rapidly progressive glomerulonephritis, lung haemorrhage, or disease of both organs, when it is known as Goodpasture’s disease. Goodpasture’s disease is more common in younger patients, while elderly patients often present with renal-limited disease. Patients with anti-GBM disease should be treated with plasma exchange combined with glucocorticoids and immunosuppressants, but early diagnosis is essential, as renal function is rarely recoverable in those requiring dialysis at presentation.

The combination of glomerulonephritis and pulmonary haemorrhage (Goodpasture’s syndrome) may also be observed with small-vessel vasculitis (particularly granulomatosis with polyangiitis, previously known as Wegener’s granulomatosis) and lupus.

Infection-related glomerulonephritis

RPGN may occur either during or following an infection. In both cases, circulating immune complexes are present and activation of the complement system promotes consumption of complement factors, resulting in low serum C3 and C4 concentration, as observed in many causes of glomerulonephritis (Box 15.17). Post-infectious glomerulonephritis is observed most commonly in children and young adults, and typically presents 10 days after a streptococcal throat infection or longer after a skin infection. The clinical presentation ranges from mild abnormalities on urinalysis to RPGN with severe AKI. The anti-streptolysin (ASO) test is positive in up to 95% of patients with streptococcal throat infections. Treatment is supportive, with control of blood pressure and fluid overload with salt restriction, diuretics and dialysis if required. Antibiotic therapy is rarely needed, as the renal disease occurs after the infection has subsided. The medium-term prognosis for children and most adults is good, with recovery of renal function typical even in those requiring dialysis therapy. Some patients may develop CKD 20–30 years after the original presentation, however.

An immune complex-mediated disease may also be observed during an infection, typically a staphylococcal infection such as endocarditis, skin infection or pneumonia, but also with subacute endocarditis due to Streptococcus viridans. This occurs more commonly in older adults and the presentation tends not to be as fulminant as with post-streptococcal disease. In addition to supportive measures, antibiotic therapy is required, as infection is usually concurrent with renal disease.

Tubulo-interstitial diseases

These diseases primarily affect the renal tubules and interstitial components of the renal parenchyma. They are characterised...
by tubular dysfunction with electrolyte abnormalities, moderate levels of proteinuria and varying degrees of renal impairment. Often the urinary output may be relatively preserved for any given GFR, and indeed there may be polyuria and nocturia.

**Acute interstitial nephritis**

Acute interstitial nephritis (AIN) is an immune-mediated disorder, characterised by acute inflammation affecting the tubulointerstitium of the kidney. It is commonly drug-induced, with proton pump inhibitors (PPIs) fast becoming the most common cause, but can be caused by other toxins, and can complicate a variety of systemic diseases and infections (Box 15.18).

**Clinical features**

The clinical presentation is typically with renal impairment but, in some patients with drug-induced AIN, there may be signs of a generalised drug hypersensitivity reaction with fever, rash and eosinophilia. Proteinuria is generally modest (PCR < 100 mg/mmol) and tubular in type (see Box 15.25, p. 412). The urine may contain white blood cells and white cell casts but is sterile on culture. Eosinophils are present in up to 70% of patients but this is a non-specific finding. AIN should always be considered in patients with non-oliguric AKI. There may be a rapid deterioration of renal function in some cases of drug-induced AIN, causing the condition to be mistaken for RPGN.

**Investigations**

Renal biopsy is usually required to confirm the diagnosis (Fig. 15.13D). This typically shows evidence of intense inflammation, with infiltration of the tubules and interstitium by polymorphonuclear leucocytes and lymphocytes. Eosinophils may also be observed, especially in drug-induced AIN. Often granulomas may be evident, especially in drug-induced AIN or sarcoidosis (p. 608). The degree of chronic inflammation in a biopsy is a useful predictor of long-term renal function. Eosinophiluria may be present but is not a good discriminator for AIN.

**Management**

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but high-dose glucocorticoids (prednisolone 1 mg/kg/day) may accelerate recovery and prevent long-term scarring. Other specific causes (see Box 15.18) should be treated, if possible.

**Chronic interstitial nephritis**

Chronic interstitial nephritis (CIN) is characterised by renal dysfunction with fibrosis and infiltration of the renal parenchyma by lymphocytes, plasma cells and macrophages, in association with tubular damage.
Pathophysiology

This disease may follow on from AIN that does not resolve, or may be associated with ingestion of various toxins and drugs, or with metabolic and chronic inflammatory diseases, as summarised in Box 15.19. In many patients, CIN presents at a late stage and no underlying cause can be identified. Genetic causes may underlie many of these cases (p. 404). Toxins that have been associated with CIN include those contained within the plant *Aristolochia clematitis* (birthwort). These are probably responsible for the severe nephrotoxicity that can be associated with treatment with herbal medicines in Asia and for Balkan nephropathy, which affects isolated rural communities in Bosnia, Bulgaria, Croatia, Romania and Serbia, possibly through contaminated flour. The nephropathy is commonly linked with tumours of the collecting system and is probably due to the mutagenic effects of the plant toxin on the urothelial epithelium. Ingestion of mushrooms within the *Cortinarius* genus can cause a devastating and irreversible renal tubular toxicity. It is encountered occasionally in Scandinavia and Scotland.

Clinical features

Most patients with CIN present in adult life with CKD, hypertension and small kidneys. Urinalysis abnormalities are non-specific. A minority present with salt-losing nephropathy, characterised by hypotension, polyuria and features of sodium and water depletion. People with CIN have an impairment of urine-concentrating ability and sodium conservation, which puts them at risk of AKI due to salt and water depletion during an acute illness. Renal tubular acidosis (p. 365) may complicate CIN but is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis and Sjögren’s syndrome.

Management

Management is supportive in nature, with correction of acidosis and hyperkalaemia; replacement of fluid and electrolytes, as required; and renal replacement therapy if irreversible renal damage has occurred.

### Papillary necrosis

The renal papillae lie within a hypertonic environment in the renal medulla, at the end of the vasa recta. They are susceptible to ischaemic damage because of this and can undergo necrosis when their vascular supply is impaired as the result of diabetes mellitus, sickle-cell disease or long-term ingestion of NSAIDs. The condition may occasionally occur in other diseases. There is an association with pyleonephritis but it is difficult to determine whether this is a cause of papillary necrosis or a complication. The clinical presentation is variable. Some patients are asymptomatic and clinically silent, whereas others present with renal colic and renal impairment as necrosed papillae slough off and cause ureteric obstruction. Urinalysis may be normal but more frequently haematuria and sterile pyuria are present. Significant proteinuria is unusual, unless there is renal failure. The imaging method of choice to make the diagnosis is CTU or intravenous pyelography. Management is based on relieving obstruction, where present, and withdrawal of the offending drugs.

### Genetic renal diseases

The advent of modern genetic techniques such as next-generation sequencing has allowed us to understand the breadth of inherited renal diseases on a much deeper level than before.

### Inherited glomerular diseases

#### Alport’s syndrome

A number of uncommon diseases may involve the glomerulus in childhood but the most important one affecting adults is Alport’s syndrome. Most cases arise from a mutation or deletion of the COL4A5 gene on the X chromosome, which encodes type IV collagen, resulting in inheritance as an X-linked recessive disorder (p. 48). Mutations in COL4A3 or COL4A4 genes are less common and cause autosomal recessive disease. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 15.14). Affected patients progress from haematuria to ESRD in their late teens or twenties. Female carriers of COL4A5 mutations usually have haematuria but less commonly develop significant renal disease. Some other basement membranes containing the same collagen isoforms are similarly involved, notably in the cochlea, so that Alport’s syndrome is associated with sensorineural deafness and ocular abnormalities.
Angiotensin-converting enzyme (ACE) inhibitors may slow but not prevent loss of kidney function. Patients with Alport’s syndrome are good candidates for renal replacement therapy (RRT), as they are young and usually otherwise healthy. They can develop an immune response to the normal collagen antigens present in the GBM of the donor kidney and, in a small minority, anti-GBM disease develops and destroys the allograft.

**Thin glomerular basement membrane disease**

In thin glomerular basement membrane disease there is glomerular bleeding, which is usually non-visible, without associated hypertension, proteinuria or a reduction in GFR. The glomeruli appear normal by light microscopy but, on electron microscopy, the GBM is abnormally thin. The condition may be familial and some patients are carriers of Alport mutations. This does not appear to account for all cases, and in many patients the cause is unclear. Monitoring of these patients is advisable, as proteinuria may develop in some and there appears to be an increased rate of progressive CKD in the long term.

**Hereditary nephrotic syndrome**

Many genes have been discovered that cause early-onset nephrotic syndrome, often with an FSGS pattern of injury. Inheritance may be autosomal dominant or recessive, the former conditions having a less severe and later-onset phenotype and often exhibiting incomplete penetrance. The involved genes almost all code for podocyte proteins, including nephrin (‘Finnish-type’ nephropathy) and podocin, which both cause early congenital nephrotic syndrome. Autosomal dominant mutations in various genes may cause FSGS as part of systemic syndromes; the genes include $\text{INF2}$ (Charcot–Marie–Tooth disease), $\text{LMX1B}$ (nail–patella syndrome) and $\text{WT1}$ (abnormal genitalia, Wilms’ tumour, mental retardation).

Inheriting variants in the $\text{APOL1}$ gene, which is observed predominantly in people of West African ancestry, leads to a greatly increased risk of kidney disease including FSGS (p. 400).

Inherited tubulo-interstitial diseases

It has become evident in recent years that a significant number of cases of CKD with low or absent proteinuria have genetic causes, which may be inherited in an autosomal dominant or recessive pattern (Box 15.20). The histological pattern of injury is identical to other forms of CIN (p. 402). This is a heterogeneous group of inherited disorders. Small cysts are sometimes evident, explaining the previous name of medullary cystic kidney disease, but tubulo-interstitial nephritis is the predominant pattern of injury. Many of these conditions, especially those formerly known as nephronophthisis, are associated with renal dystrophies and brain or other abnormalities, and some may be associated with hyperuricaemia or gout ($\text{UMOD}$ or $\text{HNF1-beta}$ mutations). Modern genetics have brought clarity to a disease spectrum comprising many different conditions with inexact previous names.

Isolated defects of tubular function

An increasing number of disorders have been identified that are caused by specific defects in transporter molecules expressed in renal tubular cells. Only the most common are mentioned here. Renal glycosuria is a benign autosomal recessive defect of tubular reabsorption of glucose, caused by mutations of the sodium/glucose co-transporter SGLT2. Glucose appears in the urine in the presence of a normal blood glucose concentration. It is notable that SGLT2 inhibitors have been developed as a treatment for diabetes mellitus and evidence suggests they may improve renal and cardiovascular outcomes.

Cystinuria is a rare condition, in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the SLC3A1 amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (p. 431).

Other uncommon tubular disorders include hereditary hypophosphataemic rickets (p. 1052), in which reabsorption of filtered phosphate is reduced; nephrogenic diabetes insipidus (p. 687), in which the tubules are resistant to the effects of vasopressin (antidiuretic hormone, ADH); and Bartter’s and Gitelman’s syndromes, in which there is sodium-wasting and hypokalaemia (p. 361).

The term ‘Fanconi’s syndrome’ is used to describe generalised proximal tubular dysfunction. The condition typically presents with low blood phosphate and uric concentrations, glycosuria, aminoaciduria and proximal renal tubular acidosis. In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi’s syndrome, notably Wilson’s disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common end-point of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes are described on page 365.

Cystic diseases of the kidney

It is common to encounter patients with a single renal cyst or even multiple cysts as an incidental finding, especially in those aged 50 years and over. Usually, these cysts are of no clinical consequence and are asymptomatic, but occasionally they can cause pain or haematuria. In addition, several specific diseases are recognised as being caused by the formation of multiple renal cysts. These are discussed in more detail below.

Adult polycystic kidney disease

Adult polycystic kidney disease (PKD) is a common condition, with a prevalence of approximately 1:1000, and is inherited as an autosomal dominant trait. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. The surrounding normal kidney tissue is compressed and progressively damaged. Mutations in the PKD1 gene account for 85% of cases and those in PKD2 for about 15% (coding for polycystin 1 and 2, respectively). ESRD occurs in approximately 50% of patients with PKD1 mutations, with a mean age of onset of 52 years, but in a minority of patients with PKD2 mutations, with a mean age of onset of 69 years. It has been estimated that between 5% and 10% of patients on RRT have PKD.

15.21 Adult polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to haemorrhage into a cyst
- Hypertension
- Haematuria (with little or no proteinuria)
- Urinary tract or cyst infections
- Renal failure

Clinical features

Common clinical features are shown in Box 15.21. Affected people are usually asymptomatic until later life but hypertension usually occurs from the age of 20 onwards. One or both kidneys may be palpable and the surface may feel nodular. About 30% of patients with PKD also have hepatic cysts (see Fig. 22.39, p. 893) but disturbance of liver function is rare. Sometimes (almost always in women) this causes massive and symptomatic hepatomegaly, usually concurrent with renal enlargement but occasionally with only minor renal involvement. Berry aneurysms of cerebral vessels are an associated feature in about 5% of patients with PKD. This feature appears to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation is frequent but rarely severe, and colonic diverticula and abdominal wall hernias may occur.

Investigations

The diagnosis is usually based on family history, clinical findings and ultrasound examination. Ultrasound demonstrates cysts in approximately 95% of affected patients over the age of 20 and is the screening method of choice, but may not detect small developing cysts in younger subjects. Cysts may also be identified by other imaging modalities, such as MRI (Fig. 15.15). Simple renal cysts may occur in normal individuals but are uncommon below the age of 30. The following criteria exist for an ultrasound diagnosis of PKD in patients with a family history but unknown genotype:

- 15–39 years of age: at least three unilateral or bilateral kidney cysts
- 40–59 years of age: at least two cysts in each kidney
- 60 years or older: at least four cysts in each kidney.

It is now possible to make a molecular diagnosis by mutation screening of PDK1 or PDK2 but this is seldom used in routine clinical practice because the PKD1 gene is so large and has many possible mutations. Next-generation sequencing allows faster and simpler genetic screening for PKD1 and PKD2. This is likely to be used in cases with an uncertain diagnosis (young patients, few cysts, lack of family history), for workup of living kidney donors, or for screening for mutations associated with a worse prognosis (see below). Screening for intracranial aneurysms is not generally indicated but can be done by MR angiography in families with a history of subarachnoid haemorrhage. The yield of screening is low, however, and the risk/benefit ratio of intervention in asymptomatic aneurysms in this disease is not clear.

Management

Blood pressure control is important because cardiovascular morbidity and mortality are so common in renal disease, but evidence is lacking that controlling blood pressure to generally recommended CKD targets (e.g., <130/80 mmHg) influences renal outcomes. There are data suggesting that targeting a very low blood pressure (<110/75 mmHg) with ACE inhibitors or angiotensin II...
causes cysts but also may cause a tubulo-interstitial pattern of injury or congenital absence of a kidney. It also causes a form of MODY (p. 733).

Autosomal recessive PKD is caused by mutations in the \textit{PKHD1} gene, encoding fibrocystin. It is less common than autosomal dominant PKD (about 1:20,000 live births). Patients often present in infancy or young childhood with renal cysts and congenital hepatic fibrosis.

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal cysts and tumours in adult life. In tuberous sclerosis (p. 1264), replacement of renal tissue by multiple angiomyolipomas may occasionally cause renal failure in adults. Patients may also develop renal cysts and have a higher risk of renal cell carcinoma. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and mental retardation). The von Hippel–Lindau syndrome (p. 1132) is associated with multiple renal cysts, renal adenomas and renal adenocarcinoma. Other involved organs include the central nervous system (haemangioblastomas), pancreas (serous cystadenomas) and adrenals (phaeochromocytoma).

A number of other rarer inherited cystic diseases are recognised that have some similarities to PKD but distinct genetic causes. Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children. Most of these seem to involute during growth, leaving a solitary kidney in adults.

Acquired cystic kidney disease can develop in patients with a very long history of renal failure, so it is not an inherited cystic disease. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma.

**Renal vascular diseases**

Diseases that affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

**Renal artery stenosis**

A stenosis of more than 50% may be observed on imaging of the renal arteries in up to 20% of older patients with advanced kidney disease; however, a haemodynamically significant effect will be present in only a relatively small proportion. Renal artery stenosis is the most common cause of secondary hypertension, with an estimated prevalence of about 2% in unselected patients, but this may increase to 4% in older patients who have evidence of atherosclerotic disease elsewhere. Most cases of renal artery stenosis are caused by atherosclerosis but fibromuscular dysplasia involving the vessel wall may be responsible in younger patients. Rare causes include vasculitis, thromboembolism and aneurysms of the renal artery.

**Pathophysiology**

Renal artery stenosis results in a reduction in renal perfusion pressure, which activates the renin–angiotensin system, leading to increased circulating levels of angiotensin II. This results in hypertension by provoking vasoconstriction and increasing aldosterone production by the adrenal, causing sodium retention by the renal tubules (p. 351). Significant reduction of renal blood flow occurs when there is more than 70% narrowing of the artery, and this is commonly associated with distal, post-stenotic

---

**Other cystic diseases**

Renal cysts and diabetes syndrome is caused by \textit{HNF1-beta} mutations (see above); it has a varying renal phenotype that often

---

**Fig. 15.15 MRI images of the kidneys.**

\textbf{A} Normal kidneys. 

\textbf{B} Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.
dilatation. Atherosclerotic lesions are typically ostial and are associated with more widespread atherosclerosis within the aorta and other vessels, particularly the iliac vessels. There is often concurrent small-vessel disease in affected kidneys, due to subclinical atheroembol. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the affected kidney and may cause renal failure if bilateral, or if unilateral in the presence of a single kidney (ischaemic nephropathy).

In younger patients, fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon disorder of unknown cause. It is characterised by hypertrophy of the media (medial fibroplasia), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have renal arteries with this appearance. It most commonly presents with hypertension in patients aged 15–30 years, and women are affected more frequently than men. Irregular narrowing (beading) may occur in the distal renal artery and this sometimes extends into the intrarenal branches of the vessel. Rarely, renal artery stenosis may occur as a complication of large-vessel vasculitis, such as Takayasu’s arteritis and polyarteritis nodosa (pp. 1041 and 1042).

Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion in about 15% of cases. This figure increases with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, at least 85% of patients with renal artery stenosis will not develop progressive renal impairment, and many patients die from coronary, cerebral or other vascular disease rather than renal failure. Unfortunately, methods of predicting which patients are at risk of progression or who will respond to treatment are still imperfect.

Clinical features
Renal artery stenosis can present in various ways including hypertension, acute pulmonary oedema, progressive renal failure (with bilateral disease) or a deterioration in renal function when ACE inhibitors or ARBs are administered. Although many patients experience a slight drop in GFR when commencing these drugs, an increase in serum creatinine of 30% or more raises the possibility of renal artery stenosis. Acute pulmonary oedema is particularly characteristic of bilateral renovascular disease. It typically occurs at night and is associated with severe hypertension, often in the context of normal or only mildly impaired renal and cardiac function. Clinical evidence of generalised vascular disease may be observed, particularly in the legs and in older patients with atherosclerotic renal artery stenosis. Clinical features associated with an increased risk of renal artery stenosis in hypertensive patients are summarised in Box 15.22. However, given the risk of imaging and angiography in patients with renal disease (see Box 15.4, p. 390), further investigation should only be performed if intervention is being contemplated (see below).

Investigations
When appropriate, imaging of the renal vasculature with either CT angiography or MR angiography should be performed to confirm the diagnosis (Fig. 15.16). Both give good views of the main renal arteries, the vessels predominantly involved and the most amenable to intervention. Biochemical testing may reveal impaired renal function and an elevated plasma renin activity, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may also reveal a discrepancy in size between the two kidneys, although this is insufficiently sensitive or specific to be of value in diagnosis of renovascular disease in hypertensive patients.

Management
The first-line management in patients with renal artery stenosis is medical therapy with antihypertensive drugs, supplemented, where appropriate, by statins and low-dose aspirin in those with atherosclerotic disease. Interventions to correct the vessel narrowing should be considered in:

- young patients (age below 40) suspected of having renal artery stenosis
- those whose blood pressure cannot easily be controlled with antihypertensive agents
- those who have a history of ‘flash’ pulmonary oedema
- those with accelerated phase (malignant) hypertension
- those whose renal function is deteriorating.

The most commonly used technique is angioplasty. The best results are obtained in non-atheromatous fibromuscular dysplasia, where correction of the stenosis has a high chance of success in improving blood pressure and protecting renal function. Beyond the indications above, angioplasty and stenting is now rarely performed if intervention is being contemplated (see below).

### 15.22 Presentation and clinical features of renal artery stenosis

Renal artery stenosis is more likely if:
- hypertension is severe, of recent onset or difficult to control
- kidneys are asymmetrical in size
- flash pulmonary oedema occurs repeatedly
- there is peripheral vascular disease of the lower limbs
- there is renal impairment
- renal function has deteriorated on angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers
- particularly with bilateral disease.

![Fig. 15.16 Renal artery stenosis. A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).](image-url)
performed in atherosclerotic disease, as randomised trials such as ASTRAL and CORAL have produced no convincing evidence for overall benefit in terms of renal function, blood pressure control or cardiovascular outcomes. The risks of angioplasty and stenting include renal artery occlusion, renal infarction and atheroemboli (p. 409) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery.

**Acute renal infarction**

This is an uncommon condition that occurs as the result of sudden occlusion of the renal arteries. The presentation is typically with loin pain of acute onset, usually in association with non-visible haematuria, but pain may be absent in some cases. Severe hypertension is common but not universal. Blood levels of lactate dehydrogenase (LDH) and CRP are commonly raised. Severe hypertension is common but not universal. Blood levels of lactate dehydrogenase (LDH) and CRP are commonly raised.

E. coli O157:H7 serotype is the best known but other serotypes that produce verotoxins may also be responsible. Although these bacteria live as commensals in the gut of cattle and other livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. Most cases are sporadic but large outbreaks related to poor sanitation may occur. In developed countries, Shiga-like toxin-associated HUS is now the most common cause of AKI in children. Recovery is good in most patients but sometimes RRT may be required for up to 14 days. No other specific treatments have been shown to accelerate renal recovery.

In the absence of bloody diarrhoea, other (atypical) causes of HUS should be considered: in particular, abnormalities of the complement system. Familial forms are due to mutations in various genes that encode components or regulators of the complement cascade, including factor H (CFH), factor B (CFB), membrane co-factor protein (MCP) and complement component 3 (C3). The penetrance of familial HUS is incomplete, indicating that environmental triggers are also involved: often infection, including diarrhoea. Sporadic cases may be associated with the development of autoantibodies to complement factor H. In addition to supportive care, including RRT if necessary, management of complement-mediated HUS includes plasma exchange to replace complement component and remove pathogenic autoantibodies. Recently, impressive results have been reported with the anti-C5 monoclonal antibody, eculizumab, which binds to C5, thereby preventing activation of the terminal complement cascade.

**Thrombotic thrombocytopenic purpura**

Like HUS, thrombotic thrombocytopenic purpura (TTP) is characterised by microangiopathic haemolytic anaemia and thrombocytopenia; in contrast, however, the brain is more commonly affected in TTP and involvement of the kidney is usually less prominent. TTP is an autoimmune disorder caused by antibodies against ADAMTS-13, which is involved in regulating platelet aggregation, and a low (<10%) serum ADAMTS-13 activity level may be useful in distinguishing TTP from HUS. This distinction is important, as early therapy with plasma exchange is crucial in TTP. More details are provided on page 979.

**Cholesterol emboli**

These present with renal impairment, haematuria, proteinuria and sometimes eosinophilia with inflammatory features that can mimic a small-vessel vasculitis. The symptoms are provoked by showers of cholesterol-containing microemboli, arising in atrophomatous plaques in major arteries. The diagnosis should be suspected when these clinical features occur in patients with widespread atheromatous disease, who have undergone interventions such as surgery or arteriography. They may also be precipitated by anticoagulants and thrombolytic agents. On clinical examination, signs of large-vessel disease and microvascular occlusion in the lower limbs (ischaemic toes, livedo reticularis) are common but not invariable (Fig. 15.17). There is no specific treatment.

**Small-vessel vasculitis**

Renal disease caused by small-vessel vasculitis usually presents with a clinical picture typical of a glomerulonephritis (see Figs 15.9 and 15.12C, pp. 393 and 399). More information is given on page 410.
by dialysis and have a poor prognosis. Where treatment is justified – for example, if there is a good chance of recovery or of a liver transplant – slow or continuous treatments are less likely to precipitate or exacerbate hepatic encephalopathy. IgA nephropathy (p. 400) is more common in patients with chronic liver disease.

### Sarcoïdosis

The most common renal manifestation of sarcoïdosis is hypercalcaemia from 1,25-vitamin D formation in granulomas. Less commonly, it may lead to a granulomatous interstitial nephritis, sometimes presenting acutely, where renal function may improve with glucocorticoid therapy. Postmortem examinations reveal a chronic interstitial nephritis in 15–30% of patients with sarcoïdosis but clinically relevant disease appears to be much less common.

### Systemic vasculitis

Small-vessel vasculitis (p. 1040) commonly affects the kidneys, with rapid and profound impairment of glomerular function. Histologically, there is a focal inflammatory glomerulonephritis, usually with focal necrosis (see Box 15.15, p. 398, and Fig. 15.12C, p. 399) and often with crescentic changes (see Fig. 15.12C). Typically, the patient is systemically unwell with an acute phase response, weight loss and arthralgia. In some patients, it presents as a kidney-limited disorder, with rapidly deteriorating renal function and crescentic nephritis (a rapidly progressive glomerulonephritis). In others, pulmonary haemorrhage may occur, which can be life-threatening.

The most important cause is ANCA vasculitis (p. 1041). Two subtypes are recognised, microscopic polyangiitis (MPA) and granulomatosis with polyangiitis. Both may present with glomerulonephritis and pulmonary haemorrhage, along with constitutional symptoms. Gastrointestinal involvement and neuropathy may also occur. Serological testing for antibodies to myeloperoxidase (MPO) and proteinase 3 (PR3) is usually positive but these are not specific and a biopsy of affected tissue should be obtained, if possible, to confirm the diagnosis.

The standard treatment of glomerulonephritis associated with systemic vasculitis is high-dose glucocorticoids combined with cyclophosphamide, or mycophenolate mofetil (p. 1041). Recent studies indicate that rituximab (p. 1006), when combined with high-dose glucocorticoids, is as effective as oral cyclophosphamide and high-dose glucocorticoids in the treatment of ANCA-associated vasculitis. Plasma exchange can offer additional benefit in patients with progressive renal damage who are not responding adequately to immunosuppressive therapy.

Glomerulonephritis secondary to vasculitis may rarely be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE usually involves the kidney in different ways (see below).

Medium- to large-vessel vasculitis, such as polyarteritis nodosa (p. 1042), does not cause glomerulonephritis but can cause hypertension, renal aneurysms and infarction if the renal vessels are involved.

### Systemic sclerosis

Renal involvement is a serious complication of systemic sclerosis, which is more likely to occur in diffuse cutaneous systemic sclerosis (DCSS) than in limited cutaneous systemic sclerosis (LCSS) (p. 1037). The renal lesion is caused by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles. There is intense intrarenal vasospasm and plasma renin activity is markedly elevated. Renal involvement usually presents clinically with severe hypertension, microangiopathic features and progressive oliguric renal failure (‘scleroderma renal crisis’). Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75% but about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after glucocorticoid use or cessation of ACE inhibitors is well described.

### Systemic lupus erythematosus

Subclinical renal involvement, with non-visible haematuria and proteinuria but minimally impaired or normal renal function, is common in systemic lupus erythematosus (SLE). Usually, this is due to glomerular disease, although interstitial nephritis may also occur, particularly in patients with overlap syndromes such as mixed connective tissue disease and Sjögren’s syndrome (p. 1039).

Almost any histological pattern of glomerular disease can be observed in SLE and the clinical presentation ranges from florid, rapidly progressive glomerulonephritis to nephrotic syndrome. The most common presentation is with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients, the most common histological pattern is a proliferative glomerulonephritis with substantial deposits of immunoglobulins on immunofluorescence. Randomised controlled trials have shown that the risk of ESRD in lupus nephritis is significantly reduced by high-dose glucocorticoids administered in combination with cyclophosphamide, usually given as regular intravenous pulses. Subsequently, it has been shown that the combination of glucocorticoids and mycophenolate mofetil is equally as effective, for both induction and maintenance treatment.

Many patients with SLE who develop ESRD go into remission, possibly because of immunosuppression related to the ESRD.
Patients with ESRD caused by SLE are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls SLE.

## Sickle-cell nephropathy

Improved survival of patients with sickle-cell disease (p. 951) means that a high proportion now live to develop chronic complications of microvascular occlusion. In the kidney, these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis may also occur (p. 403). A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor because of the haemoglobinopathy. Patients with sickle trait have an increased incidence of unexplained non-visible haematuria.

### Acute kidney injury

Acute kidney injury (AKI), previously referred to as acute renal failure, is not a diagnosis; rather it describes the situation where there is a sudden and often reversible loss of renal function, which develops over days or weeks and is often accompanied by a reduction in urine volume. Approximately 7% of all hospitalised patients and 20% of acutely ill patients develop AKI. In uncomplicated AKI mortality is low, even when RRT is required. In AKI associated with sepsis and multiple organ failure, mortality is 50–70% and the outcome is usually determined by the severity of the underlying disorder and other complications, rather than by kidney injury itself. Elderly patients are at higher risk of developing AKI and have a worse outcome (Box 15.25).

## Pathophysiology

There are many causes of AKI and it is frequently multifactorial. It is helpful to classify it into three subtypes:

- ‘pre-renal’, when perfusion to the kidney is reduced
- ‘renal’, when the primary insult affects the kidney itself
- ‘post-renal’, when there is obstruction to urine flow at any point from the tubule to the urethra (Fig. 15.18).

In pre-renal AKI, a reduction in perfusion reduces GFR. If the insult is not corrected, this may lead to ‘renal’ injury: namely, acute tubular necrosis (ATN). Histologically, the kidney shows inflammatory changes, focal breaks in the tubular basement membrane and interstitial oedema (see Fig. 15.13B, p. 402). Dead tubular cells may also be shed into the tubular lumen, leading to tubular obstruction. Although tubular cell damage is the dominant feature under the microscope, there may also be profound alterations in the renal microcirculation. Renal AKI may be caused by nephrotoxic drugs (p. 426), which can cause ATN or allergic interstitial nephritis. The other common ‘renal’ cause is glomerulonephritis, in which there is direct inflammatory damage to the glomeruli (p. 416).

Post-renal AKI occurs as the result of obstruction to the renal tract. This leads to elevation of intraluminal ureteral pressure transmitted to the nephrons after prolonged obstruction, with a subsequent fall in GFR. If the obstruction is not relieved, the low GFR is maintained by a drop in renal blood flow rate via thromboxane A₂ and angiotensin II. This leads to chronic renal injury over time (several weeks). Recovery of renal function depends on the duration of obstruction and also the pre-morbid GFR.

## Clinical features

Early recognition and intervention is important in AKI; all emergency admissions to hospital should have renal function, blood pressure, temperature and pulse checked on arrival and should undergo a risk assessment for the likelihood of developing AKI. This includes looking at coexisting diseases such as diabetes and vascular and liver disease, which make AKI more likely, as well as gathering information on drug treatments such as ACE inhibitors and NSAIDs, which may be associated with renal dysfunction. If a patient is found to have a high serum creatinine, it is important to establish whether this is an acute or acute-on-chronic phenomenon, or a sign of CKD (see Fig. 15.22, p. 416). Previous measurements of renal function can be of great value in differentiating these possibilities. Patients with AKI need to be assessed quickly to determine the likely underlying cause. Clinical features and pertinent investigations for the different causes of AKI are shown in Box 15.25. Various criteria have been proposed to classify AKI and to help identify high-risk patients, guide treatment and provide information regarding prognosis but are mostly used in a research setting to standardise diagnosis. The most commonly used are the KDIGO, AKIN and RIFLE criteria.

### Pre-renal AKI

Patients with pre-renal AKI are typically hypotensive and tachycardic with signs of poor peripheral perfusion, such as delayed capillary return. Tachycardia and postural hypotension (a fall in blood pressure of >20/10 mmHg from lying to standing) are valuable signs of early hypovolaemia. Many patients with sepsis...

(ACE = angiotensin-converting enzyme; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; ARBs = angiotensin receptor blockers; BP = blood pressure; GBM = glomerular basement membrane; HIV = human immunodeficiency virus; HUS = haemolytic uraemic syndrome; JVP = jugular venous pulse; LDH = lactate dehydrogenase; Na = sodium; NSAIDs = non-steroidal anti-inflammatory drugs; PPIs = proton pump inhibitors; TMA = thrombotic microangiopathy)

Initially present with poor peripheral perfusion, as mentioned above, but then show evidence of peripheral vasodilatation once they have undergone initial resuscitation with intravenous fluids. However, this is accompanied by relative underfilling of the arterial tree and the kidney responds as it would to absolute hypovolaemia, with renal vasoconstriction. It is important to note that pre-renal AKI may also occur without systemic hypotension, particularly in patients taking NSAIDs or ACE inhibitors (Fig. 15.19). The cause of hypotension is often obvious, but concealed blood loss can occur into the gastrointestinal tract, retroperitoneum, following trauma (particularly with pelvic and femoral fractures), and into the pregnant uterus. Large volumes of intravascular fluid may also be lost into tissues after crush injuries or burns, and in severe inflammatory skin diseases or sepsis. Uncorrected renal hypoperfusion causing pre-renal azotaemia may progress to ATN.

**Renal AKI**

Factors that can help differentiate the various causes of intrinsic renal AKI are summarised in Box 15.25. Patients with
Acute kidney injury

Management of acute kidney injury

- Assess fluid status as this will determine fluid prescription:
  - If hypovolaemic: optimise systemic haemodynamic status with fluid challenge and inotropic drugs if necessary
  - Once euolaemic, match fluid intake to urine output plus an additional 500 mL to cover insensible losses
  - If fluid-overloaded, prescribe diuretics (loop diuretics at high dose will often be required); if the response is unsatisfactory, dialysis may be required
  - Administer calcium resonium to stabilise myocardium and glucose and insulin to correct hyperkalaemia if K+ > 6.5 mmol/L (see Box 14.17, p. 363) as a holding measure until a definitive method of removing potassium is achieved (dialysis or restoration of renal function)
  - Consider administering sodium bicarbonate (100 mmol) to correct acidosis if H+ is > 100 mmol/L (pH < 7.0)
  - Discontinue potentially nephrotoxic drugs and reduce doses of therapeutic drugs according to level of renal function
  - Ensure adequate nutritional support
  - Consider proton pump inhibitors to reduce the risk of upper gastrointestinal bleeding
  - Screen for intercurrent infections and treat promptly if present
  - In case of urinary tract obstruction, drain lower or upper urinary tract as necessary

Cardiopulmonary complications

Pulmonary oedema (Fig. 15.20) may be caused by the administration of excessive amounts of fluids relative to urine output. If pulmonary oedema develops, intubation and mechanical ventilation may be necessary. Inotropic drugs (phenylephrine, dobutamine) may be required and inotropic support should be titrated to maintain a cardiac index of 2.5 L/min/m². Positive inotropic support may also be required. A chest x-ray may be required to confirm the diagnosis of pulmonary oedema.

Management

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 15.26.

Haemodynamic status

If hypovolaemia is present, it should be corrected by replacement of intravenous fluid or blood; excessive administration of fluid should be avoided, since this can provoke pulmonary oedema and worsen outcome in AKI. Monitoring of central venous pressure may be of value in determining the rate of administration of fluid in these circumstances. Balanced crystalloid solutions, such as Plasma-Lyte, Hartmann’s or Ringer’s lactate, may be preferable to isotonic saline (0.9% NaCl) when large volumes of fluid resuscitation are required, in order to avoid hyperchloremic acidosis, but whether this substantially influences outcome remains unclear. Administration of hydroxyethyl starch solutions should be avoided, since they have been associated with higher rates of established AKI. Critically ill patients may require inotropic drugs to restore an effective blood pressure but clinical trials do not support a specific role for low-dose dopamine.

Hyperkalaemia and acidosis

Fig. 15.20 Pulmonary oedema in acute kidney injury. The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

Hyperkalaemia is common, particularly in patients with rhabdomyolysis, burns, haemolysis or metabolic acidosis. Rate of increase of serum potassium concentration is usually the most important predictor of EKG abnormalities and outcome. For children, serum K+ concentration > 6.5 mmol/L or a rate of increase of > 0.5 mmol/L/h is considered significant. Serum pH often < 7.0. If serum K+ concentration is > 6.5 mmol/L, this should be treated immediately, as described in Box 14.17 (p. 363), to prevent life-threatening cardiac arrhythmias. Metabolic acidosis develops unless prevented by loss of hydrogen ions through vomiting. Severe acidosis can be ameliorated with sodium bicarbonate if volume status allows. Restoration of blood volume will correct acidosis by restoring kidney function. Infusions of isotonic sodium bicarbonate may also be used, if acidosis is severe, to reduce life-threatening hyperkalaemia (Box 15.26).

Pulmonary oedema (Fig. 15.20) may be caused by the administration of excessive amounts of fluids relative to urine output. If pulmonary oedema develops, intubation and mechanical ventilation may be necessary. Inotropic drugs (phenylephrine, dobutamine) may be required and inotropic support should be titrated to maintain a cardiac index of 2.5 L/min/m². Positive inotropic support may also be required. A chest x-ray may be required to confirm the diagnosis of pulmonary oedema.

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 15.26.

Haemodynamic status

If hypovolaemia is present, it should be corrected by replacement of intravenous fluid or blood; excessive administration of fluid should be avoided, since this can provoke pulmonary oedema and worsen outcome in AKI. Monitoring of central venous pressure may be of value in determining the rate of administration of fluid in these circumstances. Balanced crystalloid solutions, such as Plasma-Lyte, Hartmann’s or Ringer’s lactate, may be preferable to isotonic saline (0.9% NaCl) when large volumes of fluid resuscitation are required, in order to avoid hyperchloremic acidosis, but whether this substantially influences outcome remains unclear. Administration of hydroxyethyl starch solutions should be avoided, since they have been associated with higher rates of established AKI. Hyperkalaemia and acidosis

Hyperkalaemia is common, particularly in patients with rhabdomyolysis, burns, haemolysis or metabolic acidosis. Rate of increase of serum potassium concentration is usually the most important predictor of EKG abnormalities and outcome. For children, serum K+ concentration > 6.5 mmol/L or a rate of increase of > 0.5 mmol/L/h is considered significant. Serum pH often < 7.0. If serum K+ concentration is > 6.5 mmol/L, this should be treated immediately, as described in Box 14.17 (p. 363), to prevent life-threatening cardiac arrhythmias. Metabolic acidosis develops unless prevented by loss of hydrogen ions through vomiting. Severe acidosis can be ameliorated with sodium bicarbonate if volume status allows. Restoration of blood volume will correct acidosis by restoring kidney function. Infusions of isotonic sodium bicarbonate may also be used, if acidosis is severe, to reduce life-threatening hyperkalaemia (Box 15.26).
output and by increased pulmonary capillary permeability. If pulmonary oedema is present and urine output cannot be rapidly restored, treatment with dialysis may be required to remove excess fluid. Temporary respiratory support may also be necessary using non-invasive ventilation. Once initial resuscitation has been performed, fluid intake should be matched to urine output plus 500 mL per day to cover insensible losses, unless diarrhoea is present, in which case additional fluids may be required.

Electrolyte disturbances
Electrolyte disturbances, such as dilutional hyponatraemia, may occur if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. They can be avoided by paying careful attention to fluid balance and by giving intravenous fluids slowly. Modest hypocalcaemia is common but rarely requires treatment. Serum phosphate levels are usually high but may fall in patients on daily or continuous renal replacement therapy (CRRT), necessitating phosphate replacement.

Dietary measures
Adequate nutritional support should be ensured and it is important to give sufficient amounts of energy and adequate amounts of protein; high protein intake should be avoided. This is particularly important in patients with sepsis and burns who are hypercatabolic. Enteral or parenteral nutrition may be required (p. 707).

Infection
Patients with AKI are at substantial risk of intercurrent infection because humoral and cellular immune mechanisms are depressed. Regular clinical examination, supplemented by microbiological investigation where appropriate, is required to diagnose infection. If infection is discovered, it should be treated promptly according to standard principles (Ch. 6).

Medications
Patients with drug-induced kidney injury (p. 402) should have the offending drug withdrawn. Additionally, vasoactive medications, such as NSAIDs and ACE inhibitors, should be discontinued, as they may prolong AKI (see Fig. 15.19). H2-receptor antagonists or PPIs should be given to prevent gastrointestinal bleeding. Other drug treatments should be reviewed and the doses adjusted if necessary, to take account of renal function. Non-essential drug treatments should be stopped.

Renal tract obstruction
In post-renal AKI, the obstruction should be relieved as soon as possible. This may involve urinary catheterisation for bladder outflow obstruction, or correction of ureteric obstruction with a ureteric stent or percutaneous nephrostomy.

Renal replacement therapy
Conservative management can be successful in AKI with meticulous attention to fluid balance, electrolytes and nutrition, but RRT may be required in patients who are not showing signs of recovery with these measures (Box 15.26). No specific cut-off values for serum urea or creatinine have been identified at which RRT should be commenced, and clinical trials of earlier versus later RRT in unselected patients with AKI have not shown differences in outcome. Furthermore, RRT can be a risky intervention, since it requires the placement of central venous catheters that may become infected and it may represent a major haemodynamic challenge in unstable patients. Accordingly, the decision to institute RRT should be made on an individual basis, taking account of the potential risks and benefits, comorbidity and an assessment of whether early or delayed recovery is likely. Severe uraemia with pericarditis and neurological signs (uremic encephalopathy) is uncommon in AKI but, when present, is a strong indication for RRT; other indications are given in Box 15.35 (p. 422). The two main options for RRT in AKI are intermittent haemodialysis and CRRT (see Box 15.38, p. 424). Peritoneal dialysis is also an option if haemodialysis is not available (p. 424).

**Recovery from AKI**
Most cases of AKI will recover after the insult resolves but recovery may be impaired in pre-existing CKD or a prolonged severe insult (Fig. 15.21). Recovery is heralded by a gradual return of urine output and a steady improvement in plasma biochemistry. Initially, there is often a diuretic phase in which urine output increases rapidly and remains excessive for several days before returning to normal. This may be due in part to tubular damage and to temporary loss of the medullary concentration gradient. After a few days, urine volume falls to normal as the concentrating function improves, and a steady improvement occurs in plasma biochemistry. Recovery is shown by a return of normal values for serum urea or creatinine, with restoration of renal function and improvement in plasma biochemistry. Recovery may take several weeks, months, or even years, depending on the cause of AKI and the patient’s general condition. Recovery from AKI is uncommon in AKI but, when present, is a strong indication for RRT; other indications are given in Box 15.35 (p. 422). The two main options for RRT in AKI are intermittent haemodialysis and CRRT (see Box 15.38, p. 424). Peritoneal dialysis is also an option if haemodialysis is not available (p. 424).

**15.27 Acute kidney injury in old age**

- **Physiological change:** nephrons decline in number with age and average GFR falls progressively, so many elderly patients will have established CKD and less functional reserve. Small acute declines in renal function may therefore have a significant impact.
- **Creatinine:** as muscle mass falls with age, less creatinine is produced each day. Serum creatinine can be misleading as a guide to renal function.
- **Renal tubular function:** declines with age, leading to loss of urinary concentrating ability.
- **Drugs:** increased drug prescription in older people (diuretics, ACE inhibitors and NSAIDs) may contribute to the risk of AKI.
- **Causes:** infection, renal vascular disease, prostatic obstruction, hypovolaemia and severe cardiac dysfunction are common.
- **Mortality:** rises with age, primarily because of comorbid conditions.
mechanism and tubular reabsorption are restored. During the recovery phase of AKI, it may be necessary to provide temporary supplementation of bicarbonate, potassium and sometimes calcium, phosphate and magnesium.

AKI in old age is described in Box 15.27.

### Chronic kidney disease

Chronic kidney disease (CKD) refers to an irreversible deterioration in renal function that usually develops over a period of years (see Box 15.3, p. 388). Initially, it manifests only as a biochemical abnormality but, eventually, loss of the excretory, metabolic and endocrine functions of the kidney leads to the clinical symptoms and signs of renal failure, collectively referred to as uraemia. When death is likely without RRT (CKD stage 5), it is called end-stage renal disease (ESRD).

#### Epidemiology

The social and economic consequences of CKD are considerable. In many countries, estimates of the prevalence of CKD stages 3–5 (eGFR <60 mL/min/1.73 m²) are around 5–7%, mostly affecting people aged 65 years and above (see Box 15.3). The prevalence of CKD in patients with hypertension, diabetes and vascular disease is substantially higher, and targeted screening for CKD should be considered in these and other high-risk groups. More than 25% of the population aged over 75 years have an eGFR of <60 mL/min/1.73 m², mostly stage 3A CKD, which in this context typically reflects an increased cardiovascular risk burden. In these patients, investigation and management should be focused on cardiovascular risk prevention, as very few will ever develop ESRD. Many primary renal diseases, however, are more common in the elderly, so investigation is warranted for those with declining renal function or with haematuria/proteinuria on dipstick.

#### Pathophysiology

Common causes of CKD are shown in Box 15.28. In many cases, the underlying diagnosis is unclear, especially among the large number of elderly patients with stage 3 CKD (see Box 15.3).

Many patients diagnosed at a late stage have bilateral small kidneys; renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to alter management.

#### Clinical features

The typical presentation is for a raised urea and creatinine to be found incidentally during routine blood tests, often during screening of high-risk patients, such as those with diabetes or hypertension. Most patients with slowly progressive disease are asymptomatic until GFR falls below 30 mL/min/1.73 m² and some can remain asymptomatic with much lower GFR values than this. An early symptom is nocturia, due to the loss of concentrating ability and increased osmotic load per nephron, but this is non-specific. When GFR falls below 15–20 mL/min/1.73 m², symptoms and signs are common and can affect almost all body systems (Fig. 15.22). They typically include tiredness or breathlessness, which may, in part, be related to renal anaemia or fluid overload. With further deterioration in renal function, patients may suffer pruritus, anorexia, weight loss, nausea, vomiting and hiccups. In very advanced renal failure, respiration may be particularly deep (Kussmaul breathing) due to profound metabolic acidosis, and patients may develop muscular twitching, fits, drowsiness and coma.

#### Investigations

The recommended investigations in patients with CKD are shown in Box 15.29. Their main aims are:

- to exclude AKI requiring rapid investigation; in patients with unexpectedly high urea and creatinine (when there is an increase from previous results or no prior results are available), renal function should be retested within 2 weeks to avoid missing AKI
- to identify the underlying cause where possible, since this may influence the treatment
- to identify reversible factors that may worsen renal function, such as hypertension or urinary tract obstruction
- to screen for complications of CKD, such as anaemia and renal osteodystrophy
- to screen for cardiovascular risk factors.

Referral to a nephrologist is appropriate for patients with potentially treatable underlying disease and those who are likely to progress to ESRD. Suggested referral criteria are listed in Box 15.30.

#### Management

The aims of management in CKD are to:

- monitor renal function
- prevent or slow further renal damage
- limit complications of renal failure
- treat risk factors for cardiovascular disease
- prepare for RRT, if appropriate (p. 420).

#### Monitoring of renal function

The rate of change in renal function varies between patients and may vary over time in each individual. Renal function should therefore be monitored every 6 months in patients with stage 3 CKD, but more frequently in patients who are deteriorating rapidly or have stage 4 or 5 CKD. A plot of GFR against time (Fig. 15.23) can demonstrate whether therapy has been successful in slowing progression, detect any unexpected increase in the rate of decline that may warrant further investigation, and help
be employed where possible; tight blood pressure control is applicable to CKD regardless of cause, however, and reducing proteinuria is a key target in those with glomerular disease.

**Antihypertensive therapy** Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (apart from those with proteinuria; see below) and predict when ESRF will be reached to facilitate timely planning for RRT.

**Reduction of rate of progression**
Slowing the rate of progression of CKD may reduce complications and delay symptom onset and the need for RRT (Fig. 15.23). Therapies directed towards the primary cause of CKD should be employed where possible; tight blood pressure control is applicable to CKD regardless of cause, however, and reducing proteinuria is a key target in those with glomerular disease.

(ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; 25(OH)D = 25-hydroxyvitamin D)
Fig. 15.23 Plot of estimated glomerular filtration rate (eGFR) against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow), this patient entered an aggressive treatment programme aimed at optimising blood pressure (BP) and glycaemic control. The reduction in BP was accompanied by a fall in proteinuria (protein:creatinine ratio, PCR; shown in mg/mmol). At the previous rate of decline in renal function (dashed line), he was likely to reach the level of renal function at which dialysis therapy is typically required (eGFR=10 mL/min/1.73 m²) within 18 months; however, the relative stabilisation in his renal function (dotted line) means that this has been deferred, potentially for several years.

### 15.30 Criteria for referral of chronic kidney disease patients to a nephrologist

- eGFR < 30 mL/min/1.73 m²
- Rapid deterioration in renal function (> 25% from previous or > 15 mL/min/1.73 m²/year)
- Significant proteinuria (PCR > 100 mg/mmol or ACR > 70 mg/mmol), unless known to be due to diabetes and patient is already on appropriate medications
- ACR > 30 mg/mmol with non-visible haematuria
- Hypertension that remains poorly controlled despite at least four antihypertensive medications
- Suspicion of renal involvement in multisystem disease

Chronic kidney disease has additional benefits in lowering the risk of hypertensive heart failure, stroke and peripheral vascular disease. No threshold for beneficial effects has been identified and any reduction of blood pressure appears to be beneficial. Various targets have been suggested, such as 140/90 mmHg for patients with CKD and no albuminuria (ACR < 3 mg/mmol). A lower target of 130/80 mmHg should be considered for those who have moderately elevated albuminuria (ACR 3–3 mg/mmol), and is recommended for those with an ACR of more than 30 mg/mmol. Even lower targets, such as 125/75 mmHg, may be prudent in patients with CKD and heavy proteinuria (PCR > 100 mg/mmol or ACR > 70 mg/mmol). Achieving these blood pressure targets often requires multiple drugs, and therapeutic success may be limited by adverse effects and poor adherence.

**Reduction of proteinuria** Patients with proteinuria are at higher risk of progression of renal disease, and there is strong evidence that reducing proteinuria reduces the risk of progression. ACE inhibitors and ARBs reduce proteinuria and retard the progression of CKD. These effects are partly due to the reduction in blood pressure but there is evidence for a specific beneficial effect in patients with proteinuria (PCR > 50 mg/mmol or ACR > 30 mg/mmol) through a reduction in glomerular perfusion pressure. In addition, ACE inhibitors have been shown to reduce the risk of cardiovascular events and all-cause mortality in CKD. Accordingly, ACE inhibitors and/or ARBs should be prescribed to all patients with diabetic nephropathy and patients with CKD and proteinuria, irrespective of whether or not hypertension is present.

While ACE inhibitors and ARBs are excellent drugs for patients with diabetes or CKD and proteinuria, they need to be prescribed with care in certain circumstances. Initiation of treatment with ACE inhibitors and ARBs may be accompanied by an immediate reduction in GFR; patients should therefore have their renal function checked within 7–10 days of initiating or increasing the dose of an ACE inhibitor or ARB. Treatment can be continued so long as the reduction in GFR is not greater than 25% and is not progressive. Angiotensin II is critical for autoregulation of GFR in the context of low renal perfusion (see Fig. 15.1D, p. 385), and so ACE inhibitors or ARBs may exacerbate pre-renal failure (see Fig. 15.19). Patients on ACE inhibitors/ARBs should therefore be warned to stop taking the medication if they become unwell, such as with fever, vomiting or diarrhoea, restarting once they are better. This also applies to other common medications used in patients with CKD, such as diuretics, metformin and NSAIDs, and this advice may be reinforced by providing written information such as ‘sick-day rule’ cards (Box 15.31). ACE inhibitors and ARBs increase serum potassium and should not be commenced in patients with baseline potassium > 5.5 mmol/L. In patients with serum potassium > 6.0 mmol/L, the dose of ACE inhibitors or ARBs should be reduced or discontinued entirely, but only after all other measures to reduce potassium have been considered (see below). Combination therapy with ACE inhibitors and ARBs or direct renin inhibitors has not been shown to reduce progression of kidney disease but is associated with higher rates of hyperkalaemia and AKI, and is therefore to be avoided.
When you are unwell with vomiting, diarrhoea or fever, stop taking the following medications:

- ACE inhibitors: medicines ending in ‘-prl’, e.g. lisinopril, ramipril
- Angiotensin receptor blockers: medicines ending in ‘-sartan’, e.g. irbesartan, losartan, candesartan
- Non-steroidal anti-inflammatory painkillers: e.g. ibuprofen (Brufen), diclofenac (Voltarol)
- Diuretics: e.g. furosemide, bendroflumethiazide, indapamide, spironolactone
- Metformin: a medicine for diabetes.

Restart when you are well again (after 24–48 hours of eating and drinking normally).

Treatment of complications

The kidneys have many functions in addition to excretion of waste (p. 384). Treatments that substitute for all of the normal roles of the kidneys must therefore be instigated to maintain normal body homeostasis and prevent complications.

**Maintenance of fluid and electrolyte balance** The kidneys excrete waste and regulate many electrolytes, and so patients with CKD may accumulate waste products and develop electrolyte abnormalities.

Urea is a key product of protein degradation and accumulates with progressive CKD. All patients with stages 4 and 5 CKD should be given dietary advice aimed at preventing excessive consumption of protein. Severe protein restriction is not recommended, however; there is no evidence that this reduces the rate of decline in renal function but may lead to malnutrition.

Potassium often accumulates in patients with advanced CKD, who should be provided with dietary advice to reduce daily potassium intake to below 70 mmol (Box 15.32). Potassium-binding compounds limit absorption of potassium from the gut and may be a useful adjunctive therapy. Calcium resorcin is not recommended other than as a very short-term measure, as it can be associated with bowel necrosis; however, newer agents, such as zirconium cyclosilicate and patiromer, appear promising for chronic use. Other measures that may help regulate potassium include diuretic therapy and control of acidosis with sodium bicarbonate (see below). Consideration should be given to stopping or reducing drugs that elevate potassium, such as potassium-sparing diuretics and ACE inhibitors/ARBs; however, this has to be balanced against the potential benefit that such drugs may have on retarding progression of renal and cardiovascular disease, and hence withdrawal should be reserved for when other measures have failed.

The inability of the failing kidney to excrete sodium and water loads commonly leads to their accumulation, which may manifest as oedema and may drive hypertension. Patients with evidence of volume expansion should be instructed to consume a low-sodium diet (<100 mmol/24 hrs), and in severe cases fluid intake should also be restricted. Diuretics are commonly required, and as renal function deteriorates, increasing doses of potent loop diuretics or synergistic combinations of loop, thiazide and potassium-sparing diuretics may be necessary.

Occasionally, some patients with tubulo-interstitial disease can develop ‘salt-wasting’ disease and may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function.

**Acid–base balance** Reduced ability to excrete organic acids in patients with CKD may lead to an anion-gap metabolic acidosis. In addition, in patients with tubulo-interstitial disease or diabetic nephropathy, there may be specific defects in acid–base regulation within the kidney, causing a non-anion-gap renal tubular acidosis (p. 365). Although acidosis is usually asymptomatic, it may be associated with increased tissue catabolism and decreased protein synthesis, and may exacerbate bone disease and the rate of decline in renal function. Hence, plasma bicarbonate concentrations should be maintained above 22 mmol/L by prescribing sodium bicarbonate supplements (starting dose of 1 g 8-hourly, increasing as required). There is some evidence that correcting acidosis may reduce the rate of decline in renal function.

**Renal bone disease** Disturbances of calcium and phosphate metabolism are almost universal in advanced CKD (Fig. 15.24). The sequence of events that leads to renal bone disease is complex, but two primary factors are impaired excretion of phosphate and failure of the renal tubular cells to convert 25-hydroxyvitamin D to its active metabolite, 1,25-dihydroxyvitamin D. A rise in serum phosphate levels promotes production of the hormone fibroblast growth factor 23 (FGF23) from osteocytes (Fig. 24.3, p. 986) and stimulates parathyroid hormone (PTH) release and hyperplasia of the parathyroid glands. The FGF23 and PTH promote tubular phosphate excretion, thereby partly compensating for the reduced glomerular filtration of phosphate. The reduced 1,25-dihydroxyvitamin D levels impair intestinal absorption of calcium. In addition, raised levels of serum phosphate complex with calcium in the extracellular space, leading to calcium phosphate deposition. Both the reduced absorption and increased deposition of calcium cause hypocalcaemia, which also stimulates PTH production by the parathyroid glands. Hence in many patients with CKD, compensatory responses initially maintain phosphate and calcium levels at the upper and lower ends of their respective normal ranges, at the expense of an elevated PTH level (secondary hyperparathyroidism). This is associated with a gradual transfer of calcium and phosphate from the bone to other tissues, leading to bone resorption (ostitis fibrosa cystica), and in severe cases this may result in bony pain and increased risk of fractures. Conversely there is increased deposition of calcium phosphate in many tissues, most notably blood vessels and heart valves, which may contribute to the increased risk of cardiovascular disease in patients with CKD (p. 420). In some cases, tertiary hyperparathyroidism supervenes, due to autonomous production of PTH by the enlarged parathyroid glands; this presents with hypercalcaemia. Additional problems in bone metabolism include low bone turnover (adynamic bone disease) in patients who have been over-treated with vitamin D metabolites, osteomalacia with over-treatment of
Chronic kidney disease

shortness of breath. Haemoglobin can be as low as 50–70 g/L in CKD stage 5, although it is often less severe or absent in patients with polycystic kidney disease. Several mechanisms are implicated, as summarised in Box 15.33. Iron deficiency is common in patients with CKD, and even more prevalent in those on haemodialysis as a result of haemolysis in the dialysis circuit. Hence many patients require iron supplements, which may be given intravenously for those with iron intolerance or in situations where adherence may be difficult. Once iron deficiency and other causes of anaemia have been excluded or corrected, recombinant human erythropoietin is very effective in correcting the anaemia of CKD and improving symptoms. Erythropoietin treatment does not influence mortality, however, and correcting haemoglobin to normal levels may carry some extra risk, including hypertension and thrombosis. The target haemoglobin is usually between 100 and 120 g/L. Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, in particular myeloma.

hyperphosphataemia (p. 369), and osteoporosis in patients with poor nutritional intake.

The key focus in the management of renal bone disease should be directed towards the two main driving factors, hyperphosphataemia and inadequate activation of vitamin D. Hyperphosphataemia should be treated by dietary restriction of foods with high phosphate content (milk, cheese, eggs and protein-rich foods) and by the use of phosphate-binding drugs. Various drugs are available, including calcium carbonate, aluminium hydroxide, lanthanum carbonate and polymer-based phosphate binders such as sevelamer. The aim is to maintain serum phosphate values at or below 1.5 mmol/L (4.6 mg/dL) if possible, but many of these drugs are difficult to take and adherence can be a problem. Active vitamin D metabolites (either 1-α-hydroxyvitamin D or 1,25-dihydroxyvitamin D) should be administered in patients who are hypocalcaemic or have serum PTH levels more than twice the upper limit of normal. The dose should be adjusted to try to reduce PTH levels to between 2 and 4 times the upper limit of normal to limit hyperparathyroidism while avoiding over-suppression of bone turnover and adynamic bone disease, but care must be exercised in order to avoid hypercalcaemia. In patients with persistent hypercalcaemia (tertiary hyperparathyroidism), parathyroidectomy may be required. If parathyroidectomy is unsuccessful or not possible, calcimimetic agents, such as cinacalcet, may be used. These bind to the calcium-sensing receptor in the parathyroid glands and reduce PTH secretion.

Fig. 15.24 Pathogenesis of renal osteodystrophy. Low 1,25-dihydroxyvitamin D (1,25(OH)₂D) levels cause calcium malabsorption and this, combined with high phosphate levels, causes hypocalcaemia, which increases parathyroid hormone (PTH) production by the parathyroid glands. The raised level of PTH increases osteoclastic bone resorption. Although production of fibroblast growth factor 23 (FGF23) from osteocytes also increases, promoting phosphate excretion, this is insufficient to prevent hyperphosphataemia in advanced chronic kidney disease.

15.33 Causes of anaemia in chronic kidney disease

- Deficiency of erythropoietin
- Toxic effects of uraemia on marrow precursor cells
- Reduced red cell survival
- Blood loss due to capillary fragility and poor platelet function
- Reduced intake, absorption and utilisation of dietary iron

Anaemia Anaemia is common in patients with CKD and contributes to many of the non-specific symptoms, including fatigue and

shortness of breath. Haemoglobin can be as low as 50–70 g/L in CKD stage 5, although it is often less severe or absent in patients with polycystic kidney disease. Several mechanisms are implicated, as summarised in Box 15.33. Iron deficiency is common in patients with CKD, and even more prevalent in those on haemodialysis as a result of haemolysis in the dialysis circuit. Hence many patients require iron supplements, which may be given intravenously for those with iron intolerance or in situations where adherence may be difficult. Once iron deficiency and other causes of anaemia have been excluded or corrected, recombinant human erythropoietin is very effective in correcting the anaemia of CKD and improving symptoms. Erythropoietin treatment does not influence mortality, however, and correcting haemoglobin to normal levels may carry some extra risk, including hypertension and thrombosis. The target haemoglobin is usually between 100 and 120 g/L. Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, in particular myeloma.
Treatment of risk factors for cardiovascular disease

The risk of cardiovascular disease is substantially increased in patients with a GFR below 60 mL/min/1.73 m² and in those with proteinuria, the combination of reduced eGFR and proteinuria being particularly unfavourable. Patients with CKD have a higher prevalence of traditional risk factors for atherosclerosis, such as hypertension, hyperlipidaemia and diabetes; however, additional mechanisms of cardiovascular disease may also be implicated. Left ventricular hypertrophy is commonly found in patients with CKD, secondary to hypertension or anaemia. Calcification of the media of blood vessels, heart valves, myocardium and the conduction system of the heart is also common and may be due, in part, to the high serum phosphate levels. Reflecting this fact, serum FGF23 levels, which increase in response to serum phosphate, are an independent predictor of mortality in CKD. Both left ventricular hypertrophy and cardiac calcification may increase the risk of arrhythmias and sudden cardiac death, which is a much more common mode of death in patients with CKD than in the general population, particularly in those with more advanced disease and those on dialysis.

To reduce vascular risk, patients with CKD should be encouraged to adopt a healthy lifestyle, including regular exercise, and weight loss and smoking cessation where appropriate. Lipid-lowering drugs reduce cardiovascular events in patients with CKD, although their efficacy may be less once patients require dialysis.

Preparing for renal replacement therapy

It is crucial for patients who are known to have progressive CKD to be prepared well in advance for the institution of RRT. This involves ensuring that they are referred to a nephrologist in a timely manner, as those who are referred late, when they are either at the stage of or very close to requiring dialysis, tend to have poorer outcomes.

Several decisions need to be taken in discussion with the patient and family. The first is to decide whether RRT is an appropriate choice or whether conservative treatment might be preferable (p. 421). This is especially relevant in patients with significant comorbidity. For those who decide to go ahead with RRT, there are further choices between haemodialysis and peritoneal dialysis (Box 15.34), between hospital and home treatment, and on referral for renal transplantation.

Since there is no evidence that early initiation of RRT improves outcome, the overall aim is to commence RRT when symptoms of CKD begin to impact on quality of life but before serious complications have occurred. While there is wide variation between patients, this typically occurs when the eGFR approaches 10 mL/min/1.73 m². This may be a useful marker to predict the timing of initiation of RRT by extrapolating from a plot of serial eGFR measurements over time (see Fig. 15.23).

Preparations for starting RRT should begin at least 12 months before the predicted start date. This involves providing the patient with psychological and social support, assessing home circumstances and discussing the various choices of treatment (Fig. 15.25). Depression is common in patients who are on or approaching RRT, and support from the renal multidisciplinary team should be provided both for them and for their relatives, to explain and help them adapt to the changes to lifestyle that may be necessary once RRT starts; this may help to reduce their anxieties about these changes. Physical preparations include establishment of timely access for haemodialysis or peritoneal dialysis and vaccination against hepatitis B.

Renal replacement therapy

Renal replacement therapy (RRT) may be required on a temporary basis in patients with AKI or on a permanent basis for those with advanced CKD. Since the advent of long-term RRT in the 1960s, the numbers of patients with ESRD who are kept alive by dialysis and transplantation have increased considerably. By the end of 2014, almost 59,000 patients were on RRT in the UK, with a median age of 65 years. After a long period of expansion, the number of patients on dialysis in the UK and USA has begun to stabilise; however, the total number of patients on RRT continues to expand, due to an increasing proportion (53%) of patients with a functional transplant. The remaining patients were on haemodialysis (41%) and peritoneal dialysis (6%).

There are variations in the numbers of patients receiving RRT in different countries because of differences in the incidence of predisposing disease, as well as differences in medical practice. For example, the incidence rate for RRT in the USA was about three times higher than in the UK (363 versus 115 patients per million population), and the prevalence rate was more than twice as high (2,034 versus 913 per million population). Diabetic kidney disease is the most common cause of ESRD in many countries, accounting for 26% of all ESRD in the UK and almost 50% in the USA. The large increase in the prevalence of type 2 diabetes in developing countries is resulting in a predictable rise in cases of ESRD, which is challenging already stretched health-care resources.

Survival on dialysis is strongly influenced by age and presence of complications such as diabetes (Fig. 15.26). For this reason, conservative care rather than RRT may be a more appropriate option for older patients or those with extensive comorbidities.

Although many young patients without extrarenal disease lead
Renal replacement therapy

Patients are offered full medical, psychological, and social support to optimise and sustain their existing renal function, and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. When quality of life on dialysis is poor, it is appropriate to consider discontinuing it, following discussion with the patient and family, and to offer palliative care.

Haemodialysis

Haemodialysis is the most common form of RRT in ESRD and is also used in AKI. Haemodialysis involves gaining access to the circulation, either through a central venous catheter or an arteriovenous fistula or graft. The patient’s blood is pumped through a haemodialyser, which allows bidirectional diffusion of normal and active lives on RRT, those aged 30–34 have a mortality rate 25 times higher than that of age-matched controls.

The aim of RRT is to replace the excretory functions of the kidney and to maintain normal electrolyte concentrations and fluid balance. Various options are available, including haemodialysis, haemofiltration, haemodiafiltration, peritoneal dialysis, and renal transplantation, and each of these is discussed in more detail below. Indications for starting RRT in both AKI and CKD may be found in Box 15.35.

Conservative treatment

In older patients with multiple comorbidities, conservative treatment of stage 5 CKD, aimed at limiting the adverse symptoms of ESRD without commencing RRT, is increasingly viewed as a positive choice (Box 15.36). Current evidence suggests that survival of these patients without dialysis can be similar or only slightly shorter than that of patients who undergo RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological, and social support to optimise and sustain their existing renal function and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. When quality of life on dialysis is poor, it is appropriate to consider discontinuing it, following discussion with the patient and family, and to offer palliative care.
In AKI, dialysis is performed through a large-bore, dual-lumen catheter inserted into the femoral or internal jugular vein (Fig. 15.27A). Subclavian lines are avoided where possible, largely due to bleeding risk. Also, thromboses or stenoses here will compromise the ability to form a functioning fistula in the arm if the patient fails to recover renal function and needs chronic dialysis.

**Haemodialysis in AKI**

Haemodialysis offers the best rate of small solute clearance in AKI, compared with other techniques such as haemofiltration, but should be started gradually because of the risk of delirium and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1–2 hours of dialysis is prescribed initially but, subsequently, patients with AKI who are haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day. During dialysis, it is standard practice to anticoagulate patients with heparin but the dose may be reduced if there is a bleeding risk. Epoprostenol can be used as an alternative but carries a risk of hypotension. In patients undergoing short treatments and in those with abnormal clotting, it may be possible to avoid anticoagulation altogether.

**Haemodialysis in CKD**

In CKD, vascular access for haemodialysis is gained by formation of an arteriovenous fistula (AVF), usually in the forearm, up to a year before dialysis is contemplated (Fig. 15.27B). After 4–6 weeks, increased pressure transmitted from the artery to the vein leading from the fistula causes distension and thickening of the vessel wall (arterialisation). Large-bore needles can then be

inserted into the vein to provide access for each haemodialysis treatment.

Preservation of arm veins is thus very important in patients with progressive renal disease who may require haemodialysis in the future. If creation of an AVF is not possible, synthetic polytetrafluoroethylene (PTFE) grafts may be fashioned between an artery and a vein, or central venous catheters may be used for short-term access (Fig. 15.27C). These are tunneled under the skin to reduce infection risk. All patients must be screened in advance for hepatitis B, hepatitis C and HIV, and vaccinated against hepatitis B if they are not immune. All dialysis units should have segregation facilities for hepatitis B-positive patients, given its easy transmissibility. Patients with hepatitis C and HIV are less infectious and can be treated satisfactorily using machine segregation and standard infection control measures.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The intensity and frequency of dialysis should be adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%; below this level there is an associated increase in mortality. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. The intensity of dialysis can be increased by:

• escalating the number of standard sessions to four or more per week
• performing short, frequent dialysis sessions of 2–3 hours 5–7 times per week
• performing nocturnal haemodialysis, when low blood-pump speeds and single-needle dialysis are used for approximately 8 hours overnight 5–6 times per week.

More frequent dialysis and nocturnal dialysis can achieve better fluid balance and phosphate control, improve left ventricular mass and possibly improve mortality, although the latter has not yet been robustly demonstrated. Box 15.37 summarises some of the problems related to haemodialysis.

Haemofiltration

This technique is principally used in the treatment of AKI as CRRT (Box 15.38). Large volumes of water are filtered from blood across a porous semipermeable membrane under a pressure gradient. Solutes are removed via ‘solvent drag’. Replacement fluid of a suitable electrolyte composition is added to the blood after it exits the haemofilter. If removal of fluid is required, then less fluid is added back than is removed (see Fig. 15.25B). Haemofiltration may be either intermittent or continuous, and typically 1–2 L of filtrate is replaced per hour (equivalent to a GFR of 15–30 mL/min/1.73 m²); higher rates of filtration may be of benefit in patients with sepsis and multi-organ failure. In continuous arteriovenous haemofiltration (CAVH), the extracorporeal blood circuit is driven by the arteriovenous pressure difference, but poor filtration rates and clotting of the filter are common and this treatment has fallen out of favour. Continuous venovenous haemofiltration (CVVH) is pump-driven, providing a reliable extracorporeal circulation. Issues concerning anticoagulation are similar to those for haemodialysis, but may be more problematic because longer or continuous anticoagulation is necessary.

Haemodiafiltration

This technique combines haemodialysis with approximately 20–30 L of ultrafiltration (with replacement of filtrate) over a 3–5-hour treatment. It uses a large-pore membrane and combines the improved clearance of medium-sized molecules observed in haemofiltration with the higher small-solute clearance of haemodialysis. It is sometimes used in the treatment of AKI, often as continuous therapy (Box 15.38). It is increasingly favoured in the treatment of CKD but is more expensive than haemodialysis and the long-term benefits are not yet established.

15.38 Types of continuous renal replacement therapy (CRRT) used in AKI management

- CVVH: continuous venovenous haemofiltration
- CVVHD: continuous venovenous haemodialysis
- CVVHDF: continuous venovenous haemofiltration

*Most CRRT machines may perform all of these treatments. Continuous arteriovenous treatments (i.e. continuous arteriovenous haemofiltration) have fallen out of favour.

Peritoneal dialysis

Peritoneal dialysis is primarily used in the treatment of CKD, though it may occasionally be employed in AKI. It requires the insertion of a permanent Silastic catheter into the peritoneal cavity (see Fig. 15.25C). Two types are in common use. In continuous ambulatory peritoneal dialysis (CAPD), about 2 L of sterile, isotonic dialysis fluid are introduced and left in place for approximately 4–6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose or glucose polymer; this results in net removal of fluid from the patient during each cycle, due to diffusion of water from the blood through the peritoneal membrane down an osmotic gradient (ultrafiltration). The patient is mobile and able to undertake normal daily activities. Automated peritoneal dialysis (APD) is similar to CAPD but uses a mechanical device to perform the fluid exchanges during the night, leaving the patient free, or with only a single exchange to perform, during the day.

CAPD is particularly useful in children, as a first treatment in adults with residual renal function, and as a treatment for elderly patients with cardiovascular instability. The long-term use of peritoneal dialysis may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, including encapsulating peritoneal sclerosis, but some patients have been treated successfully for more than 10 years. Box 15.39 summarises some of the problems related to CAPD treatment.

Renal transplantation

Renal transplantation offers the best chance of long-term survival in ESRD and is the most cost-effective treatment. All patients with ESRD should be considered for transplantation but many are not suitable due to a combination of comorbidity and advanced age (although no absolute age limit applies). Active malignancy, vasculitis, cardiovascular disease and a high risk of recurrence of renal disease (generally glomerulonephritides) are common contraindications to transplantation.

Kidney grafts may be taken from a deceased donor in the UK after brain death (40%) or circulatory death (24%), or from a living donor (36%). As described on page 88, matching of a donor to a specific recipient is strongly influenced by immunological factors, since graft rejection is the major cause of transplant failure. Compatibility of ABO blood group between donor and recipient is usually required and the degree of matching for major histocompatibility (MHC) antigens, particularly human leucocyte antigen DR (HLA-DR), influences the incidence of rejection. Immediately prior to transplantation, cross-matching should be performed for anti-HLA antibodies (traditionally mixing of recipient serum with donor lymphocytes) (p. 88). Positive tests predict early rejection and worse graft survival. Although some ABO- and HLA-incompatible transplants are now possible, this involves appropriate preparation with pre-transplant plasma exchange and/or immunosuppression, so that recipient antibodies to the donor’s tissue are reduced to acceptably low levels. This option is generally only available for living donor transplants because of the preparation required. Paired exchanges, in which a donor–recipient pair who are incompatible, either in blood group or HLA, are computer-matched with another pair to overcome the mismatch, are also used to help increase the number of successful transplants that can be performed.

During the transplant operation, the kidney is placed in the pelvis; the donor vessels are usually anastomosed to the recipient’s external iliac artery and vein, and the donor ureter to the bladder (see Fig. 15.25D). The native kidneys are usually left in place but may be removed pre-transplant if they are a source of repeated sepsis or to make room for a transplant in patients with very large kidneys due to adult polycystic kidney disease.
Renal replacement therapy

• 425

used initially due to impaired wound healing. Antibodies to deplete or modulate specific lymphocyte populations are increasingly used for induction and for treatment of glucocorticoid-resistant acute rejection. Basiliximab, an interleukin (IL)-2 receptor antagonist, is frequently used at induction to lower rates of rejection. Acute cellular rejection is usually treated, in the first instance, by short courses of high-dose glucocorticoids, such as intravenous methylprednisolone on three consecutive days. Anti-lymphocyte preparations (e.g., anti-thymocyte globulin, ATG) are used for glucocorticoid-resistant rejection. Antibody-mediated rejection is more difficult to treat and usually requires plasma exchange.

All transplant patients require regular life-long follow-up to monitor renal function and complications of immunosuppression. Allograft dysfunction is often asymptomatic and picked up during routine surveillance blood tests. The common causes at different time points post transplant are summarised in Box 15.40. Immunosuppressive therapy (see Box 4.26, p. 89) is required to prevent rejection and is more intensive in the early post-transplantation period, when rejection risk is highest. A common regimen is triple therapy with prednisolone; ciclosporin or tacrolimus; and azathioprine or mycophenolate mofetil. Sirolimus is an alternative that can be introduced later but is generally not used initially due to impaired wound healing. Antibodies to deplete or modulate specific lymphocyte populations are increasingly used for induction and for treatment of glucocorticoid-resistant acute rejection. Basiliximab, an interleukin (IL)-2 receptor antagonist, is frequently used at induction to lower rates of rejection. Acute cellular rejection is usually treated, in the first instance, by short courses of high-dose glucocorticoids, such as intravenous methylprednisolone on three consecutive days. Anti-lymphocyte preparations (e.g., anti-thymocyte globulin, ATG) are used for glucocorticoid-resistant rejection. Antibody-mediated rejection is more difficult to treat and usually requires plasma exchange.

### 15.39 Problems with continuous ambulatory peritoneal dialysis

<table>
<thead>
<tr>
<th>Problem</th>
<th>Clinical features</th>
<th>Cause</th>
<th>Treatment</th>
</tr>
</thead>
</table>
| Peritonitis              | Cloudy drainage fluid; abdominal pain and systemic sepsis are variable | Usually entry of skin contaminants via catheter; bowel organisms less common | Culture of peritoneal dialysis fluid
Intraperitoneal antibiotics, tobramycin, vancomycin
Catheter removal sometimes required |
| Catheter exit site infection | Erythema and pus around exit site                      | Usually skin organisms                                               | Antibiotics; sometimes surgical drainage      |
| Ultrafiltration failure   | Fluid overload                                        | Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient | Replacement of glucose with synthetic, poorly absorbed polymers for some exchanges (icodextrin) |
| Peritoneal membrane failure | Inadequate clearance of urea etc.                     | Scarring/damage to peritoneal membrane                               | Increase in exchange volumes; consideration of automated peritoneal dialysis or switch to haemodialysis |
| Sclerosing peritonitis    | Intermittent bowel obstruction Malnutrition           | Unknown; typically occurs after many years                            | Switch to haemodialysis (may still progress)
Surgery and tamoxifen may be used |

|                      | Later (IgA nephropathy/membranoproliferative glomerulonephritis) |                                                                         |

*Time from organ retrieval in the donor, with cold perfusion occurring ex vivo, until implantation into the recipient. (FSGS = focal segmental glomerulosclerosis; HLA = human leucocyte antigen; IgA = immunoglobulin A; MCGN = mesangiocapillary glomerulonephritis; SLE = systemic lupus erythematosus)
and intravenous immunoglobulin (p. 89). Complications of immunosuppression include infections and malignancy (p. 89). Approximately 50% of white patients develop skin malignancy by 15 years after transplantation.

The prognosis after kidney transplantation is good. Recent UK statistics for transplants from cadaver donors indicate 96% patient survival and 93% graft survival at 1 year, and 88% patient survival and 84% graft survival at 5 years. Even better figures are obtained with living donor transplantation (91% graft survival at 5 years).

### Renal disease in pregnancy

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy (Box 15.41), the manifestations of others are modified during pregnancy, and a few diseases, such as pre-eclampsia (see Box 30.8, p. 1276), are unique to pregnancy. These are discussed in detail in Chapter 30.

#### 15.41 Renal diseases in pregnancy

- **Eclampsia**: severe hypertension, encephalopathy and fits
- **Disseminated intravascular coagulation**
- **Thrombotic microangiopathy**: may also occur post-partum (post-partum thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome)
- **Acute fatty liver of pregnancy**
- **HELLP** syndrome: haemolysis, elevated liver enzymes, low platelets (thrombotic microangiopathy with abnormal liver function)

### Renal disease in adolescence

Many causes of renal failure present during infancy or childhood, such as congenital urological malformations and inherited disorders like cystinosis and autosomal recessive polycystic kidney disease. The consequences continue throughout the patient’s life and the situation often arises whereby patients transition from paediatric to adult nephrology services. Some of the issues and challenges surrounding this transition are summarised in Box 15.42.

#### 15.42 Kidney disease in adolescence

- **Adherence**: young adults moving from parental supervision may become disengaged. There may also be reduced adherence to prophylactic and therapeutic treatment.
- **Adverse events**: there is an increased risk of transplant loss and other adverse events in young adults on renal replacement therapy.
- **Management**: joint transition clinics should be established with the paediatric team to facilitate transfer to adult specialist clinics.

### Drugs and the kidney

#### Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the countercurrent system. The same applies to certain toxins.

Toxic renal damage may occur by a variety of mechanisms (Box 15.43). Very commonly, drugs contribute to the development of acute tubular necrosis as one of multiple insults. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. Other types, however, especially those associated with extensive fibrosis, are less likely to be reversible.

### Non-steroidal anti-inflammatory drugs

Impairment of renal function may develop in patients on NSAIDs, since prostaglandins play an important role in regulating renal blood flow by vasodilating afferent arterioles (see Fig. 15.19, p. 413). This is particularly likely in patients with other disorders, such as volume depletion, heart failure, cirrhosis, sepsis and pre-existing renal impairment. In addition, idiosyncratic immune reactions may occur, causing minimal change nephrotic syndrome, membranous nephropathy (p. 400) and acute interstitial nephritis (p. 402). Analgesic nephropathy (p. 403) is now a rare complication of long-term use.

#### ACE inhibitors

These abolish the compensatory angiotensin II-mediated vasoconstriction of the glomerular efferent arteriole that takes place in order to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Figs 15.1 and 15.19, pp. 385 and 413). Monitoring of renal function before and after initiation of therapy is essential and an expected rise in creatinine of about 20% is frequently observed.

### Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney and so the presence of renal impairment alters the required dose and frequency (p. 31).

### Infections of the urinary tract

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 6). The urinary tract can become infected with various bacteria but the most common is *E. coli* derived from the gastrointestinal tract. The most common presenting problem is cystitis with urethritis (generally referred to as urinary tract infection).

### Urinary tract infection

Urinary tract infection (UTI) is the term used to describe acute urethritis and cystitis caused by a microorganism. It is a common disorder, accounting for 1–3% of consultations in general medical practice. The prevalence of UTI in women is about 3% at the age of 20, increasing by about 1% in each subsequent decade. In males, UTI is uncommon, except in the first year of life and in men over 60, when it may complicate bladder outflow obstruction.
Pathophysiology

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors, to which virulent strains of *E. coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter and the absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and virulence of the bacteria. Conditions that predispose to UTI are shown in Box 15.44.

Clinical features

Typical features of cystitis and urethritis include:
- abrupt onset of frequency of micturition and urgency
- burning pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- non-visible or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread to cause acute pyelonephritis. This is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an indication for hospitalisation. Only about 30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by perineal or suprapubic pain, pain on ejaculation and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (p. 340) and urethritis associated with reactive arthritis (p. 1031). Some patients, usually female, have symptoms suggestive of urethritis and cystitis but no bacteria are cultured from the urine (the ‘urethral syndrome’). Possible explanations include infection with organisms not readily cultured by ordinary
Methods (such as Chlamydia and certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes pyelonephritis, acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In hospital, E. coli still predominates but Klebsiella and streptococci are becoming more common. Certain strains of E. coli have a particular propensity to invade the urinary tract.

Investigations

An approach to investigation is shown in Box 15.45. In an otherwise healthy woman with a single lower urinary tract infection, urine culture prior to treatment is not mandatory. Investigation is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection, such as the immunocompromised, those with diabetes or an indwelling catheter, and older people (Box 15.46). The diagnosis can be made from the combination of typical clinical features and abnormalities on urinalysis. Most urinary pathogens can reduce nitrate to nitrite, and neutrophils and nitrates can usually be detected in symptomatic infections by urine dipstick tests for leucocyte esterase and nitrite, respectively. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what is a ‘significant’ culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, more than $10^5$ organisms/mL is usually regarded as significant (asymptomatic bacteriuria; see below).

Typical organisms causing UTI in the community include E. coli derived from the gastrointestinal tract (about 75% of infections), Proteus spp., Pseudomonas spp., streptococci and Staphylococcus epidermidis. In hospital, E. coli still predominates but Klebsiella and streptococci are becoming more common. Certain strains of E. coli have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in children, men or patients with recurrent infections (see Box 15.45).

Management

Antibiotics are recommended in all cases of proven UTI (Box 15.47). If urine culture has been performed, treatment may be started while awaiting the result. For infection of the lower urinary tract, treatment for 3 days is the norm and is less likely to induce significant alterations in bowel flora than more prolonged therapy. Trimethoprim or nitrofurantoin is the usual first choice of drug for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Trimethoprim and nitrofurantoin are not recommended if eGFR is <30 mL/min/1.73m² due to reduced efficacy/increased risk of toxicity. In addition, trimethoprim may increase serum potassium and creatinine levels and lead to artefactual reductions in eGFR, which resolve once the drug is discontinued. Quinolone antibiotics such as ciprofloxacin and norfloxacin, and cefalexin are also generally effective. Co-amoxiclav and amoxicillin are no longer recommended as blind therapy, as up to 30% of organisms are resistant. They may be used once cultures confirm that the organism is sensitive. Penicillins and cephalosporins are safe to use in pregnancy but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

1 In all cases, the choice of drug should take locally determined antibiotic resistance patterns into account. 2 See Hartford nomogram (Fig. 6.18, p. 122).

In more severe infection, antibiotics should be continued for 7–14 days. Seriously ill patients may require intravenous therapy with gentamicin for a few days (Box 15.47), later switching to an oral agent.

A fluid intake of at least 2 L/day is usually recommended, although this is not based on evidence and may make symptoms of dysuria worse.

**Persistent or recurrent UTI**

If the causative organism persists on repeat culture despite treatment, or if there is reinfection with any organism after an interval, then an underlying cause is more likely to be present (see Box 15.44) and more detailed investigation is justified (see Box 15.45). In women, recurrent infections are common and investigation is justified only if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic reflux nephropathy, p. 430).

If an underlying cause cannot be treated, suppressive antibiotic therapy (see Box 15.47) can be used to prevent recurrence and reduce the risk of sepsis and renal damage. Urine should be cultured at regular intervals; a regimen of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 15.48). Trimethoprim or nitrofurantoin is recommended for prophylaxis. Alternative antibiotics include cefalexin, co-amoxiclav and ciprofloxacin, but these should be avoided if possible because of adverse effects and the generation of resistance.

**Asymptomatic bacteriuria**

This is defined as more than $10^5$ organisms/mL in the urine of apparently healthy asymptomatic patients. Approximately 1% of children under the age of 1 year, 1% of schoolgirls, 0.03% of schoolboys and men, 3% of non-pregnant adult women and 5% of pregnant women have asymptomatic bacteriuria. It is increasingly common in those aged over 65. There is no evidence that this condition causes renal scarring in adults who are not pregnant and have a normal urinary tract, and, in general, treatment is not indicated. Up to 30% will develop symptomatic infection within 1 year, however. Treatment is required in infants, pregnant women and those with urinary tract abnormalities.

**Catheter-related bacteriuria**

In patients with a urinary catheter, bacteriuria increases the risk of Gram-negative bacteraemia five-fold. Bacteriuria is common,
Acute pyelonephritis

The kidneys are infected in a minority of patients with UTI. Acute renal infection (pyelonephritis) presents as a classic triad of loin pain, fever and tenderness over the kidneys. The renal pelvis is inflamed and small abscesses are often evident in the renal parenchyma (see Fig. 15.13C, p. 402).

Renal infection is almost always caused by organisms ascending from the bladder, and the bacterial profile is the same as for lower urinary tract infection (p. 428). Rarely, bacteriaemia may give rise to renal or perinephric abscesses, most commonly due to staphylococci. Predisposing factors, such as cysts or renal scarring, facilitate infection.

Rarely, acute pyelonephritis is associated with papillary necrosis. Fragments of renal papillary tissue are passed per urethra and can be identified histologically. They may cause ureteric obstruction and, if this occurs bilaterally or in a single kidney, it may lead to AKI. Predisposing factors include diabetes mellitus, chronic urinary obstruction, analgesic nephropathy and sickle-cell disease. A necrotising form of pyelonephritis with gas formation, ‘emphysematous pyelonephritis’, is occasionally seen in patients with diabetes mellitus. Xanthogranulomatous pyelonephritis is a chronic infection that can resemble renal cell cancer. It is usually associated with obstruction, is characterised by accumulation of foamy macrophages and generally requires nephrectomy. Infection of cysts in polycystic kidney disease (p. 405) calls for prolonged antibiotic treatment.

Appropriate investigations are shown in Box 15.45 and management is described above and in Box 15.47. Intravenous rehydration may be needed in severe cases. If complicated infection is suspected or response to treatment is not prompt, urine should be re-cultured and renal tract ultrasound performed to exclude urinary tract obstruction or a perinephric collection. If obstruction is present, drainage by a percutaneous nephrostomy or ureteric stent should be considered.

Tuberculosis

Tuberculosis of the kidney and renal tract is secondary to tuberculosis elsewhere (p. 588) and is the result of blood-borne infection. Initially, lesions develop in the renal cortex; these may ulcerate into the renal pelvis and involve the ureters, bladder, epididymis, seminal vesicles and prostate. Calcification in the kidney and stricture formation in the ureter are typical.

Clinical features may include symptoms of bladder involvement (frequency, dysuria); haematuria (sometimes macroscopic); malaise, fever, night sweats, lassitude and weight loss; loin pain; associated genital disease; and chronic renal failure as a result of urinary tract obstruction or destruction of kidney tissue.

Neutrophils are present in the urine but routine urine culture may be negative (‘sterile pyuria’). Special techniques of microscopy and culture may be required to identify tubercle bacilli and are most usefully performed on early morning urine specimens. Bladder involvement should be assessed by cystoscopy. Radiology of the urinary tract and a chest X-ray to look for pulmonary tuberculosis are mandatory. Anti-tuberculous chemotherapy follows standard regimens (p. 592). Surgery to relieve urinary tract obstruction or to remove a very severely infected kidney may be required.

Reflux nephropathy

This condition, which was previously known as chronic pyelonephritis, is a specific type of chronic interstitial nephritis associated with vesico-ureteric reflux (VUR) in early life and with the appearance of scars in the kidney, as demonstrated by various imaging techniques. About 12% of patients in Europe requiring treatment for ESRD may have this disorder but diagnostic criteria are imprecise.

Pathophysiology

Reflux nephropathy is thought to be due to chronic reflux of urine from the bladder into the ureters, in association with recurrent UTI in childhood. It was previously assumed that ascending infection was necessary for progressive renal damage in patients with VUR but there is evidence to suggest that renal scars can occur, even in the absence of infection. Furthermore, epidemiological surveys and controlled trials have found that efforts to correct VUR by using surgical or other means are ineffective in halting progression of the disease.

Susceptibility to VUR has a genetic component and may be associated with renal dysplasia and other congenital abnormalities of the urinary tract. It can be connected with outflow obstruction, usually caused by urethral valves, but usually occurs with an apparently normal bladder.

Clinical features

Usually, the renal scarring and dilatation are asymptomatic and the patient may present at any age with hypertension (sometimes severe), proteinuria or features of CKD. There may be no history of overt UTI. However, symptoms arising from the urinary tract may be present and include frequency of micturition, dysuria and aching lumbar pain. VUR may occur in children but diminishes as the child grows, and usually has disappeared by adulthood.

Urinalysis often shows the presence of leucocytes and moderate proteinuria (<1 g/24 hrs) but these are not invariable. The risk of renal stone formation is increased. A number of women first present with hypertension and/or proteinuria in pregnancy. Children and adults with small or unilateral renal scars have a good prognosis, provided renal growth is normal. With significant unilateral scars there is usually compensatory hypertrophy of the contralateral kidney. In patients with more severe bilateral disease, prognosis is related to the severity of renal dysfunction, proteinuria and proteinuria. If the serum creatinine is normal and hypertension and proteinuria are absent, then the long-term prognosis is usually good.

Investigations

Renal scarring can be detected by ultrasound but it has poor sensitivity and is only capable of detecting major defects and excluding significant obstruction. Radionuclide DMSA scans are more sensitive (see Fig. 15.6, p. 390), and serial imaging by MRI or CT may be useful in assessing progression. Abnormalities may be unilateral or bilateral and of any grade of severity. Gross scarring of the kidneys, commonly at the poles, is seen, with reduced kidney size and narrowing of the cortex and medulla. Renal scars may be juxtaposed to dilated calyces. In patients who develop heavy proteinuria and hypertension, renal biopsies show glomerulomegaly and focal glomerulosclerosis, probably as a secondary response to reduced nephron numbers. Radionuclide
techniques can also be used to demonstrate VUR as a non-invasive alternative to micturating cystourethrogram (MCUG; the bladder is filled with contrast medium through a urinary catheter and images are taken during and after micturition; Fig. 15.28). As surgical intervention for VUR has declined in popularity (see below), however, this type of imaging is used less often.

Management

Infection, if present, should be treated; if recurrent, it should be prevented with prophylactic therapy, as described for UTI (p. 429). If recurrent pyelonephritis occurs in an abnormal kidney with minimal function, nephrectomy may be indicated. Occasionally, hypertension is cured by the removal of a diseased kidney when the disease is predominantly or entirely unilateral.

As most childhood reflux tends to disappear spontaneously and trials have shown small or no benefits from anti-reflux surgery, such intervention is now less common. Severe reflux may be managed by ureteric reimplantation or subtrigonal injection of Teflon or polysaccharide (STING) beneath the ureteric orifice.

Urolithiasis

Renal stone disease is common, affecting people of all countries and ethnic groups. In the UK, the prevalence is about 1.2%, with a lifetime risk of developing a renal stone by age 60–70 of approximately 7% in men. In some regions, the risk is higher, most notably in countries such as Saudi Arabia, where the lifetime risk of developing a renal stone in men aged 60–70 is just over 20%.

Pathophysiology

Urinary calculi consist of aggregates of crystals, usually containing calcium or phosphate in combination with small amounts of proteins and glycoproteins. The most common types are summarised in Box 15.49. A number of risk factors have been identified for renal stone formation (Box 15.50). In developed countries, however, most calculi occur in healthy young men, in whom investigations reveal no clear predisposing cause. Renal stones vary greatly in size, from sand-like particles anywhere in the urinary tract to large, round stones in the bladder. In developing countries, bladder stones are common, particularly in children. In developed countries, the incidence of childhood bladder stones is low; renal stones in adults are more common. Staghorn calculi fill the whole renal pelvis and branch into the calyces (Fig. 15.29); they are usually associated with infection and composed largely of struvite. Deposits of calcium may be present throughout the renal parenchyma, giving rise to fine calcification within it (nephrocalcinosis), especially in patients with renal tubular acidosis, hyperparathyroidism, vitamin D intoxication and healed renal tuberculosis. Cortical nephrocalcinosis may occur in areas of cortical necrosis, typically after AKI in pregnancy or other severe AKI.

Clinical features

The clinical presentation is highly variable. Many patients with renal stone disease are asymptomatic, whereas others present with pain, haematuria, UTI or urinary tract obstruction. A common presentation is with acute loin pain radiating to the anterior
Fig. 15.29 Computed tomogram of the kidneys, ureters and bladder (CTKUB): coronal view showing a staghorn calculus in the left kidney. Courtesy of Dr I. Mendichovszky, University of Cambridge.

Patients with symptoms of renal colic should be investigated to determine whether or not a stone is present, to identify its location and to assess whether it is causing obstruction. About 90% of stones contain calcium and these can be visualised on plain abdominal X-ray (radio-opaque stones) but non-contrast CTKUB (Fig. 15.29) is the gold standard for diagnosing a stone within the kidney or ureter, as 99% are visible using this method. Ultrasound can show stones within the kidney and dilatation of the renal pelvis and ureter if the stone is obstructing urine flow; it is useful in unstable patients or young women, in whom exposure to ionising radiation is undesirable.

A minimum set of investigations (Box 15.51) should be performed in patients with a first renal stone. The yield of more detailed investigation is low, and hence usually reserved for young patients, those with recurrent or multiple stones, or those with complicated or unexpected presentations. Chemical analysis of stones is often helpful in defining the underlying cause. Since most stones pass spontaneously through the urinary tract, ideally the urine should be sieved for a few days after an episode of colic in order to collect the calculus for analysis.

**Management**

The immediate treatment of renal colic is with analgesia and antiemetics. Renal colic is often unbearably painful and demands powerful analgesia; diclofenac orally or as a suppository (100 mg) is often very effective, followed by morphine (10–20 mg) or pethidine (100 mg) intramuscularly. Around 90% of stones of less than 4 mm diameter pass spontaneously, but this applies to only 10% of stones bigger than 6 mm, and these may require intervention (see below). Patients with renal or ureteric stones are at high risk of infection; if surgery is contemplated, the patient should be covered with appropriate antibiotics. Immediate action is required if infection occurs in the stagnant urine proximal to the stone (pyonephrosis), and in patients with a solitary kidney who develop anuria in association with a stone in the ureter.

Stones that do not pass spontaneously through the urinary tract may need to be removed surgically, using ureteroscopy and stone fragmentation usually with a laser, or percutaneous nephrolithotomy (PCNL) and fragmentation with an ultrasonic disaggregator. Alternatively, stones can be fragmented by extracorporeal shock wave lithotripsy (ESWL), in which shock waves generated outside the body are focused on the stone, breaking it into small pieces that can pass easily down the ureter. The indications for intervention to manage or remove stones from the renal tract are summarised in Box 15.52. Procedures vary, depending on the site (Fig. 15.30).

Measures to prevent further stone formation are guided by the investigations in Box 15.51. Some general principles apply to almost every patient with calcium-containing stones (Box 15.53). More specific measures apply to some types. Urate stones can be prevented by allopurinol but its role in patients with calcium
Diseases of the collecting system and ureters

• Stones and high urate excretion is uncertain. Stones formed in cystinuria can be reduced by penicillamine therapy. It may also be helpful to attempt to alkalinise the urine with sodium bicarbonate, as a high pH discourages urate and cystine stone formation.

Congenital abnormalities

Various congenital anomalies of the urinary tract can occur (Fig. 15.31); they affect more than 10% of infants. If not immediately lethal, they can lead to complications in later life, including obstructive nephropathy and CKD.

Single kidneys

About 1 in 500 infants is born with only one kidney. Although this is usually compatible with normal life, it may be associated with other abnormalities.

Medullary sponge kidney disease

Medullary sponge kidney is a congenital disorder characterised by malformation of the papillary collecting ducts in the pericalyceal region of the renal pyramids. This leads to the formation of microscopic and large medullary cysts. Patients often present as adults with renal stones but the prognosis is generally good. The diagnosis is made by ultrasound, CT or intravenous urography, where contrast medium is seen to fill dilated or cystic tubules, which are sometimes calcified.

**Clinical presentation**

- Obstruction and/or anuria
- Pyonephrosis associated with stone
- Stone in a patient with solitary kidney
- Severe pain and persistence of stone in renal tract
- Pain and persistence of stone in renal tract

**Procedure**

- Emergency nephrostomy or stent
- Urgent PCNL, stent, ESWL or ureteroscopy
- Urgent PCNL, stent, ESWL or ureteroscopy
- Elective PCNL, ESWL or ureteroscopy

**Indications for intervention to manage and remove stones from the urinary tract**

(ESWL = extracorporeal shock wave lithotripsy; PCNL = percutaneous nephrolithotomy)

**Measures to prevent calcium stone formation**

**Diet**

- **Fluid**
  - At least 2 L output per day (intake 3–4 L): check with 24-hr urine collections
  - Intake distributed throughout the day (especially before bed)

- **Sodium**
  - Restrict intake

- **Protein**
  - Moderate, not high

- **Calcium**
  - Maintain good calcium intake (calcium forms an insoluble salt with dietary oxalate, lowering oxalate absorption and excretion)
  - Avoid calcium supplements separate from meals (increase calcium excretion without reducing oxalate excretion)

- **Oxalate**
  - Avoid foods that are rich in oxalate (spinach, rhubarb)

**Drugs**

- **Thiazide diuretics**
  - Reduce calcium excretion
  - Valuable in recurrent stone-formers and hypercalciuria

- **Allopurinol**
  - If urate excretion high (unproven except for urate stones)
  - Avoid
    - Vitamin D supplements (increase calcium absorption and excretion)
    - Vitamin C supplementation (increases oxalate excretion)
Complications (i.e. stones).

Symptoms, reduction of more than 10% in renal function or and/or reimplantation) may, however, be needed for recurrent surgery (narrowing of the ureter reduced renal function are treated. Ideally, treatment is expectant there is obstruction to urine flow. Patients with symptoms or pressure/flow studies may be needed to determine whether refluxing. Some 50% of cases are asymptomatic but patients may present with pain, haematuria or infection. Radiographic megaureter is a ureter dilated to more than 5 mm in diameter.

A ureterocele occurs behind a pin-hole ureteric orifice when the intramural part of the ureter dilates and bulges into the bladder. It can become very large and cause lower urinary tract obstruction. Incision of the pin-hole opening relieves the obstruction.

Ectopic ureters occur with congenital duplication of one or both kidneys (duplex kidneys). Developmentally, the ureter has two main branches and, if this arrangement persists, the two ureters of the duplex kidneys may drain separately into the bladder. The lower pole moiety enters the bladder superiorly and laterally, while the upper pole moiety enters the bladder inferomedially to the lower pole moiety ureter or, more rarely, enters the vagina or seminal vesicle. The lower pole moiety has an ineffective valve mechanism, so that urine passes up the ureter on voiding (vesico-ureteric reflux, p. 430), whereas the upper pole moiety is often associated with a ureterocele.

A megaureter is a ureter dilated to more than 5 mm in diameter. It may be obstructed or non-obliterated and refluxing or non-refluxing. Some 50% of cases are asymptomatic but patients may present with pain, haematuria or infection. Radiographic and pressure/flow studies may be needed to determine whether there is obstruction to urine flow. Patients with symptoms or reduced renal function are treated. Ideally, treatment is expectant with antibiotic prophylaxis. Surgery (narrowing of the ureter and/or reimplantation) may, however, be needed for recurrent symptoms, reduction of more than 10% in renal function or complications (i.e. stones).

Pelvi-ureteric junction obstruction

Pelvi-ureteric junction obstruction (PUJO) causes idiopathic hydronephrosis and results from a functional obstruction at the junction of the ureter and renal pelvis. The abnormality is likely to be congenital and is often bilateral. It can be seen in very young children but gross hydronephrosis may present at any age. The common presentation is ill-defined renal pain or ache, exacerbated by drinking large volumes of liquid (Dietl's crisis). Rarely, it is asymptomatic. The diagnosis is often suspected after ultrasound or CT scan, and can be confirmed with a 99mTc-MAG3 renogram followed by diuretic. In a PUJO, the MAG3 renogram shows a pathognomonic ‘rising curve’ as the radioisotope accumulates in the renal pelvis and still does not drain following the diuretic injection. Treatment is surgical excision of the pelvi-ureteric junction and reanastomosis (pyeloplasty), which can now be performed laparoscopically. Less invasive alternatives are also possible, including balloon dilatation and endoscopic pyelotomy, but are generally less effective.

Retroperitoneal fibrosis

Fibrosis of the retroperitoneal connective tissues may encircle and compress the ureter(s), causing obstruction. The fibrosis is most commonly idiopathic but can represent a reaction to infection, radiation or aortic aneurysm, or be caused by metastatic cancer. It is recognised as part of the spectrum of disorders associated with elevated IgG4 levels (p. 890). Rarely, it can be associated with inflammatory bowel disease. Patients usually present with ill-defined symptoms of ureteric obstruction. Typically, there is an acute phase response (high CRP and ESR, and polyclonal hypergammaglobulinaemia). Imaging with CT or IVU shows ureteric obstruction with medial deviation of the ureters. Idiopathic retroperitoneal fibrosis may respond well to glucocorticoids (with a reduction in inflammatory marker levels) but ureteric stenting is often necessary to relieve obstruction and preserve renal function. Failure to improve indicates the need for surgery (ureterolysis), both to relieve obstruction and to exclude malignancy.

Tumours of the kidney and urinary tract

Several malignant tumours can affect the kidney and urinary tract, including renal cell cancer, upper urinary tract urothelial cancers, bladder carcinoma, prostate carcinoma, and cancers of the testis and penis. The urogenital tract can also be affected by benign tumours and secondary tumour deposits, which can cause obstructive uropathy. Renal cell cancer and bladder carcinoma are described here, while prostate cancer (p. 438) and testicular tumours (p. 439) are covered later in this chapter.

Renal cell cancer

Renal cell cancer (RCC) is by far the most common malignant tumour of the kidney in adults, making up 2.5% of all adult cancers, with a prevalence of 16 cases per 100 000 population. It is twice as common in males. The peak incidence is between 65 and 75 years of age and it is uncommon before 40. The tumour arises from renal tubular cells. Haemorrhage and necrosis give the cut surface a characteristic mixed golden-yellow and red appearance (Fig. 15.32B). Microscopically, clear cell RCCs are the most common histological subtype (85%), with papillary,
Tumours of the kidney and urinary tract

• 435

15 renal-related morbidity. Patients at high operative risk who have small tumours may also be treated percutaneously by cryotherapy or radiofrequency ablation. There is an evolving role for active surveillance with serial imaging in selected patients with small renal masses of less than 4 cm. Surgery may also play a role in the treatment of solitary metastases, since these can remain single for long periods and excision may be curative.

RCC is resistant to most chemotherapeutic agents. For many years, cytokine therapy with interferon and interleukin-2 was used in metastatic renal cancer but, in recent years, two new classes of targeted drugs have been introduced and are now the mainstay of therapy. These are the tyrosine kinase inhibitors sunitinib and pazopanib, and the mammalian target of rapamycin (mTOR) inhibitors temsirolimus and everolimus.

In previous years, patients who presented with distant metastases were treated with cytoreductive nephrectomy, in which nephrectomy was coupled with systemic cytokine treatment, since this was shown to improve survival as compared with either treatment in isolation. It is, at present, unclear whether this survival benefit still prevails with the newer agents mentioned above.

Studies that antedate the introduction of these new agents show that, if the tumour is confined to the kidney, 5-year survival is 75%, but this falls to 5% when there are distant metastases.

Clinical features

In 50% of patients, asymptomatic renal tumours are identified as an incidental finding during imaging investigations carried out for other reasons. Among symptomatic patients, about 60% present with haematuria, 40% with loin pain and 25% with a palpable mass. About 10% present with a triad of pain, haematuria and a mass; this usually represents advanced disease. A remarkable range of systemic effects may be present, including fever, raised ESR, polycythaemia, disorders of coagulation, hypercalcaemia, and abnormalities of plasma proteins and liver function tests. The patient may present with pyrexia of unknown origin (PUO) or, rarely, with neuropathy. Some of these systemic effects are caused by secretion of products by the tumour, such as renin, erythropoietin, parathyroid hormone-related protein (PTHrP) and gonadotrophins. The effects disappear when the tumour is removed but may reappear when metastases develop.

Investigations

Ultrasound is often the initial investigation and allows differentiation between solid tumour and simple renal cysts. If the results are suggestive of a tumour, contrast-enhanced CT of the abdomen and chest should be performed for staging (Fig. 15.32A). For tumours with no evidence of metastatic spread and when the nature of the lesion is uncertain, ultrasound or CT-guided biopsy may be used to avoid nephrectomy for benign disease.

Management

Radical nephrectomy that includes the perirenal fascial envelope is the treatment of choice. Nephrectomy is commonly performed laparoscopically, with equivalent outcomes to open surgery. Partial nephrectomy, which may be carried out by open or minimally invasive surgery, is recommended for tumours of 4 cm or less, as there is a lower incidence of long-term cardiac- and renal-related morbidity. Patients at high operative risk who have small tumours may also be treated percutaneously by cryotherapy or radiofrequency ablation. There is an evolving role for active surveillance with serial imaging in selected patients with small renal masses of less than 4 cm. Surgery may also play a role in the treatment of solitary metastases, since these can remain single for long periods and excision may be curative.

RCC is resistant to most chemotherapeutic agents. For many years, cytokine therapy with interferon and interleukin-2 was used in metastatic renal cancer but, in recent years, two new classes of targeted drugs have been introduced and are now the mainstay of therapy. These are the tyrosine kinase inhibitors sunitinib and pazopanib, and the mammalian target of rapamycin (mTOR) inhibitors temsirolimus and everolimus.

In previous years, patients who presented with distant metastases were treated with cytoreductive nephrectomy, in which nephrectomy was coupled with systemic cytokine treatment, since this was shown to improve survival as compared with either treatment in isolation. It is, at present, unclear whether this survival benefit still prevails with the newer agents mentioned above.

Studies that antedate the introduction of these new agents show that, if the tumour is confined to the kidney, 5-year survival is 75%, but this falls to 5% when there are distant metastases.

Urothelial tumours

Tumours arising from the transitional epithelium of the renal tract can affect the renal pelvis, ureter, bladder or urethra. They are rare under the age of 40, affect men 3–4 times more often than women, and account for about 3% of all malignant tumours. The bladder is by far the most frequently affected site. Although almost all tumours are transitional cell carcinomas (otherwise known as urothelial cancers), squamous carcinoma may occur in urothelium that has undergone metaplasia, usually following chronic inflammation due to stones or schistosomiasis. The appearance of a transitional cell tumour ranges from a delicate papillary structure with a relatively good prognosis to a solid ulcerating mass in more aggressive disease.
**Pathophysiology**

Risk factors include cigarette smoking and exposure to industrial carcinogens such as aromatic amines, aniline dyes and aldehydes.

**Clinical features**

More than 80% of patients present with painless, visible haematuria. It should be assumed that such bleeding is from a tumour until proven otherwise (p. 391). Tumours of the ureter or bladder may also cause symptoms of obstruction, depending on the site of involvement, and tumours of the bladder present with dysuria or storage symptoms. Physical examination is usually unremarkable, except in patients with very advanced disease, when bimanual examination may reveal a palpable mass.

**Investigations**

Cystoscopy (usually flexible cystoscopy under a local anaesthetic) is mandatory to evaluate the bladder in cases of haematuria or suspected bladder cancer. Imaging of the upper urinary tract (CT urogram is the gold standard but IVU combined with renal ultrasound is also acceptable) is also important to rule out abnormalities of the kidney, ureters and renal pelvis in patients with haematuria. If a suspicious defect is seen on CT urography or IVU in the ureter or renal pelvis, a retrograde ureteropyelogram, ureteroscopy and biopsy are required. If evidence of a solid invasive urothelial tumour is found, CT of the abdomen, pelvis and chest should be performed to define tumour stage.

**Management**

Most bladder tumours are low-grade superficial lesions that can be successfully treated endoscopically by transurethral resection of the tumour. Intravesical chemotherapy with mitomycin C is usually administered as a one-off treatment post resection to prevent tumour recurrence, or may be given as a prolonged course to treat multiple low-grade bladder tumours. Patients with carcinoma in situ have a high risk of progression to invasive cancer. These patients often respond well to intravesical bacille Calmette–Guérin (BCG) treatment but more radical treatment may also be needed if this is unsuccessful. Following initial treatment and endoscopic clearance of bladder tumours, regular check cystoscopies are required to look for evidence of recurrence. Patients with recurrences of superficial disease can usually be treated by further resection and diathermy, but if this is unsuccessful, a cystectomy may be needed.

The management of invasive bladder tumours involves radical cystectomy with urinary diversion into an incontinent ileal conduit or a continent catheterisable bowel pouch; the latter is usually reserved for patients under the age of 70 years. The prognosis of bladder tumours depends on tumour stage and grade. About 5% of patients with low-grade superficial bladder cancer progress to develop invasion of the bladder muscle, compared with about 50% of those with high-grade superficial bladder cancers. Overall, the 5-year survival for patients with muscle-invasive bladder cancer of either grade is 50–70%.

Urothelial cell carcinoma of the renal pelvis and ureter is usually treated by open or laparoscopic nephro-ureterectomy, but if the tumour is solitary and low-grade, it can be treated endoscopically.

**Urinary incontinence**

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation, especially in older people (Box 15.54). The prevalence of any form of incontinence in all females is 25–45%, with a concomitant socioeconomic burden.

**Pathophysiology**

As urine accumulates in the bladder during the storage phase, the sphincter tone gradually increases, but there are no significant changes in vesical pressure, detrusor pressure or intra-abdominal pressure. During voiding, intravesical pressure increases as a result of detrusor contraction and the sphincter relaxes, allowing urine to flow from the bladder until it is empty. Clinical disorders associated with incontinence are connected with various abnormalities in this cycle and these are discussed in more detail below.

**Stress incontinence**

This occurs because passive bladder pressure exceeds the urethral pressure, due either to poor pelvic floor support or a weak urethral sphincter. Usually there is an element of both these factors. Stress incontinence is very common in women and seen most frequently following childbirth. It is rare in men and usually follows surgery to the prostate. The presentation is with incontinence during coughing, sneezing or exertion. In women, perineal inspection may reveal leakage of urine when the patient coughs.

**Urg e incontinence**

This usually occurs because of detrusor over-activity, which produces an increased bladder pressure that overcomes the urethral sphincter. Urgency with or without incontinence may also be driven by a hypersensitive bladder resulting from UTI or a bladder stone. Detrusor over-activity is usually idiopathic, multiple angiomyolipomas (tubers) may occasionally cause renal failure in adults; they may also bleed, requiring embolisation. The von Hippel–Lindau syndrome (p. 1132) is associated with multiple renal cysts, renal adenomas and clear cell renal cell cancers. Other organs affected include the central nervous system (haemangioblastomas), pancreas and adrenals (phaeochromocytoma).

**Inherited tumour syndromes affecting the renal tract**

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal tumours in adult life. In tuberous sclerosis (p. 1264), replacement of renal tissue by

---

**15.54 Incontinence in old age**

- **Prevalence:** urinary incontinence affects 15% of women and 10% of men aged over 65 years.
- **Cause:** incontinence may be transient and due to delirium, urinary infection, medication (such as diuretics), faecal impaction or restricted mobility, and these should be treated before embarking on further specific investigation.
- **Detrusor over-activity:** established incontinence in old age is most commonly due to detrusor over-activity, which may be caused by damage to central inhibitory centres or local detrusor muscle abnormalities.
- **Catheterisation:** poor manual dexterity or cognitive impairment may necessitate the help of a carer to assist with intermittent catheterisation.
other than in patients with neurological conditions such as spina bifida or multiple sclerosis, in whom it is neurogenic (p. 1093). The incidence of urge incontinence increases with age, occurring in 10–15% of the population aged over 65 years and in approximately 50% of patients requiring nursing home care. It is also seen in men with lower urinary tract obstruction and most often remits after the obstruction is relieved.

Continual incontinence
This is suggestive of a fistula, usually between the bladder and vagina (vesicovaginal), or the ureter and vagina (ureterovaginal). It is most common following gynaecological surgery but is also seen in patients with gynaecological malignancy or post radiotherapy. In parts of the world where obstetric services are scarce, prolonged obstructed labour can be a common cause of vesicovaginal fistulae. Continual incontinence may also be seen in infants with congenital ectopic ureters. Occasionally, stress incontinence is so severe that the patient leaks continuously.

Overflow incontinence
This occurs when the bladder becomes chronically over-distended and may lead to AKI (high-pressure chronic urinary retention). It is most commonly seen in men with benign prostatic enlargement or bladder neck obstruction (see below) but may arise in either sex as a result of failure of the detrusor muscle (atonic bladder). The latter may be idiopathic but more commonly is the result of damage to the pelvic nerves, either from surgery (commonly, hysterectomy or rectal excision), trauma or infection, or from compression of the cauda equina by disc prolapse, trauma or tumour. Incontinence due to prostatic enlargement can be regarded as a type of overflow incontinence.

Post-micturition dribble
This is very common in men, even in the relatively young. It is due to a small amount of urine becoming trapped in the U-bend of the bulbar urethra, which leaks out when the patient moves. Post-micturition dribble is more pronounced if associated with a urethral diverticulum or urethral stricture. It may occur in women with a urethral diverticulum and may mimic stress incontinence.

Clinical features
Patients should be encouraged to keep a voiding diary, including the measured volume voided, frequency of voiding, a note of incontinence pad usage, precipitating factors and associated features, such as urgency, since this can be of diagnostic value. Structured questionnaires may help objectively quantify symptoms. The patient should be assessed for evidence of cognitive impairment and impaired mobility. A neurological assessment should be performed to detect disorders such as multiple sclerosis that may affect the nervous supply of the bladder, and the lumbar spine should be inspected for features of spina bifida occulta. Perineal sensation and anal sphincter tone should be assessed. Rectal examination is needed to assess the prostate in men and to exclude faecal impaction as a cause of incontinence. Genital examination should be done to identify phimosis or paraphimosis in men, and vaginal mucosal atrophy, cystoceles or rectoceles in women.

Investigations
Urinalysis and culture should be performed in all patients. Ultrasound examination can be helpful in identifying patients with overflow incontinence who have incomplete bladder emptying, as they may reveal a significant amount of fluid in the bladder (>100 mL) post micturition. Urine flow rates and full urodynamic assessment by cystometrography may be required to diagnose the type of incontinence and are indicated in selected cases when the diagnosis is unclear on clinical grounds. A CT scan and cystoscopy should be performed in patients with continual incontinence who are suspected of having a fistula. Imaging with MRI is indicated when a urethral diverticulum is suspected.

Management
Weight reduction in obese patients will aid resolution of incontinence. Women with stress incontinence respond well to physiotherapy. The mainstay of treatment for urge incontinence is bladder retraining, which involves teaching patients to hold more urine voluntarily in their bladder, assisted by anticholinergic medication. Surgery may be required in patients who have severe daytime incontinence despite conservative treatment. The treatment of incontinence secondary to fistula formation is surgical. Patients with overflow incontinence due to bladder obstruction should be treated surgically or with long-term catheterisation (intermittent or continuous). Incontinence secondary to neurological diseases can be managed by intermittent self-catheterisation.

Prostate disease

Prostatitis
This results from inflammation of the prostate gland. Acute or chronic bacterial prostatitis can be caused by infection with the same bacteria that are associated with UTI (p. 426) but prostatitis can also be ‘non-bacterial’, in which case no organism can be cultured from the urine. This is also known as chronic pelvic pain syndrome. Clinical features of prostatitis include frequency, dysuria, painful ejaculation, perineal or groin pain, difficulty passing urine and, in acute disease, considerable systemic disturbance. The prostate is enlarged and tender. Bacterial prostatitis is confirmed by a positive culture from urine or from urethral discharge obtained after prostatic massage, and the treatment of choice is a quinolone antibiotic. A 4–6-week course of antibiotics is required (see Box 15.47, p. 429). Treatment of chronic pelvic pain syndrome is challenging but some patients respond to a combination of α-blockers, NSAIDs and amitriptyline.

Benign prostatic enlargement
Benign prostatic enlargement (BPE) is extremely common. It has been estimated that about half of all men aged 80 years and over will have lower urinary tract symptoms associated with bladder outlet obstruction (BOO) due to BPE. Benign prostatic hyperplasia (BPH) is the histological abnormality that underlies BPE.

Pathophysiology
The prostate gland increases in volume by 2.4 cm³ per year on average from 40 years of age. The process begins in the periurethral (transitional) zone and involves both glandular and stromal tissue to a variable degree. The cause is unknown, although BPE does not occur in patients with hypogonadism, suggesting that hormonal factors may be important.

Clinical features
The primary symptoms of BPE arise because of difficulty in voiding urine due to obstruction of the urethra by the prostate; these voiding symptoms consist of hesitancy, poor urinary flow and a sensation of incomplete emptying. Other storage
symptoms include urinary frequency, urgency of micturition and urge incontinence, although these are not specific to BPE. Some patients present suddenly with acute urinary retention, when they are unable to micturate and develop a painful, distended bladder. This is often precipitated by excessive alcohol intake, constipation or prostatic infection. Severity of symptoms can be ascertained by using the International Prostate Symptom Score (IPSS) questionnaire (Box 15.55), which serves as a valuable starting point for assessment of the patient. Once a baseline value is established, any improvement or deterioration may be monitored on subsequent visits. The IPSS may be combined with a quality-of-life score, in which patients are asked the following question: ‘If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that?’ Responses range from 0 (delighted) to 6 (terrible).

Patients may also present with chronic urinary retention. Here, the bladder slowly distends due to inadequate emptying over a long period of time. Patients with chronic retention can also develop acute retention: so-called acute-on-chronic retention. This condition is characterised by pain-free bladder distension, which may result in hydroureter, hydronephrosis and renal failure (high-pressure chronic retention, of which nocturnal incontinence is a pathognomonic symptom). On digital rectal examination (DRE), patients with BPE have evidence of prostatic enlargement with a smooth prostate gland. Abdominal examination may also reveal evidence of bladder enlargement in patients with urinary retention.

Investigations

The diagnosis of BOO secondary to BPE is a clinical one but flow rates can be accurately measured with a flow meter, post-void residual volume of urine assessed with ultrasound, and prostate volume by transrectal ultrasound scan (TRUS). Objective assessment of obstruction is possible by urodynamics. If symptoms or signs, such as a palpable bladder, nocturnal enuresis, recurrent UTI or a history of renal stones, are present, renal function should be assessed; if it is abnormal, screening should be conducted for evidence of obstructive uropathy by ultrasound examination.

Management

Patients who present with acute retention require urgent treatment and should undergo immediate catheterisation to relieve the obstruction. Those with mild to moderate symptoms can be treated by medication (Box 15.56). The first-line treatments are $\alpha_1$-adrenoceptor blockers such as tamsulosin, which reduce the tone of smooth muscle cells in the prostate and bladder neck, thereby reducing the obstruction. The 5$\alpha$-reductase inhibitors finasteride and dutasteride inhibit conversion of testosterone to the nine times more potent dihydrotestosterone in the prostate and so cause the prostate to reduce in size. This class of drugs is indicated in patients with an estimated prostate size of more than 30 g or a prostate-specific antigen (PSA) level of more than 1.4 ng/mL. Patients who fail to respond to a single drug may be treated with a combination of $\alpha$-blockers and 5$\alpha$-reductase inhibitors, since this is more efficacious than either agent alone.

Symptoms that are resistant to medical therapy require surgical treatment to remove some of the prostate tissue that is causing urethral obstruction. This is usually achieved by transurethral resection of the prostate (TURP) but enucleation of the prostate by holmium laser or vaporisation by potassium-titanyl-phosphate (KTP) laser (Greenlight laser) is equally effective and has potentially fewer complications. Open surgery is rarely needed, unless the gland is very large.

Prostate cancer

Prostate cancer is the most common malignancy in men in the UK, with a prevalence of 105 per 100,000 population. It is also common in northern Europe and the USA (particularly in the African American population) but is rare in China and Japan. It is uncommon in India but the incidence is increasing. Prostate cancer rarely occurs before the age of 50 and has a mean age at presentation of 70 years.

Pathophysiology

Prostate cancers tend to arise within the peripheral zone of the prostate and almost all are adenocarcinomas. Metastatic spread to pelvic lymph nodes occurs early and metastases to bone, mainly the lumbar spine and pelvis, are common. Genetic factors are known to play an important role in pathogenesis,
and multiple genetic loci have been found to predispose to the disease in genome-wide association studies. A family history of prostate cancer greatly increases a man’s chances of developing the disease.

**Clinical features**

Most patients either are asymptomatic or present with lower urinary tract symptoms indistinguishable from BPE. On DRE the prostate may feel nodular and stony-hard, and the median sulcus may be lost, but up to 45% of tumours are palpable. Symptoms and signs due to metastases are much less common at the initial presentation but may include back pain, weight loss, anaemia and obstruction of the ureters.

**Investigations**

Measurement of PSA levels in a peripheral blood sample, together with DRE, is the cornerstone of diagnosis. Prior to a PSA test, men should be given careful counselling about the limitations of the test: namely, a normal level does not exclude prostate cancer, while a high value does not confirm the diagnosis but will open a discussion about biopsy and possible exclusions. Measurement of PSA levels in a peripheral blood sample, with a serum PSA of 4.0–10 ng/mL or more will have prostate cancer. Occasionally, a small focus of tumour is found incidentally in patients undergoing TURP for benign hyperplasia. If the diagnosis of prostate cancer is confirmed, staging should be performed by pelvic MRI to assess the presence and extent of local involvement. An isotope bone scan should be carried out if distant metastases are suspected (rare if the PSA is below 20 ng/mL); very high levels of serum PSA (>100 ng/mL) almost always indicate distant bone metastases. Following diagnosis, serial assessment of PSA levels is useful for monitoring response to treatment and disease progression.

**Management**

Tumour confined to the prostate is potentially curable by radical prostatectomy, radical radiotherapy or brachytherapy (implantation of small radioactive particles into the prostate). These options should be considered only in patients with more than 10 years’ life expectancy. Patients who are found to have small-volume, low-grade disease do not appear to require specific treatment but should be followed up periodically with PSA testing, DRE and a schedule of biopsies; this is known as active surveillance. Prostatic cancer, like breast cancer, is sensitive to steroid hormones; metastatic prostate cancer is treated by androgen depletion, involving either surgery (orchiectomy) or, more commonly, androgen-suppressing drugs. Androgen receptor blockers, such as bicalutamide or cyproterone acetate, may also prevent tumour cell growth. Gonadotrophin-releasing hormone (GnRH) analogues, such as goserelin, continuously occupy pituitary receptors, preventing them from responding to the GnRH pulses that normally stimulate luteinising hormone (LH) and follicle-stimulating hormone (FSH) release. This initially causes an increase in testosterone before producing a prolonged reduction, and for this reason the initial dose must be covered with an androgen receptor blocker to prevent a tumour flare.

A small proportion of patients fail to respond to endocrine treatment. A larger number respond for a year or two but then the disease progresses. Chemotherapy with docetaxel can then be effective and provide a modest (around 3 months) survival advantage. Radiotherapy is useful for localised bone pain but the basis of treatment remains pain control by analgesia (p. 1331). Provided that patients do not die of another cause, the 10-year survival rate of patients with tumours localised to the prostate is 95%, but if metastases are present, this falls to 10%. Life expectancy is not reduced in patients with small foci of tumour.

### Testicular tumours

Testicular tumours are uncommon, with a prevalence of 5 cases per 100 000 population. They occur mainly in young men aged between 20 and 40 years. They often secrete α-fetoprotein (AFP) and β-human chorionic gonadotrophin (β-hCG), which are useful biochemical markers for both diagnosis and prognosis. Seminoma and teratoma account for 85% of all tumours of the testis. Leydig cell tumours are less common.

Seminomas arise from seminiferous tubules and represent a relatively low-grade malignancy. Metastases can occur through lymphatic spread, however, and typically involve the lungs. Teratomas arise from primitive germinal cells and tend to occur at a younger age than seminomas. They may contain cartilage, bone, muscle, fat and a variety of other tissues, and are classified according to the degree of differentiation. Well-differentiated tumours are the least aggressive; at the other extreme, trophoblastic teratoma is highly malignant. Occasionally, teratoma and seminoma occur together.

Leydig cell tumours are usually small and benign but secrete oestrogens, leading to presentation with gynaecomastia (p. 657).
Clinical features and investigations
The common presentation is incidental discovery of a painless testicular lump, although some patients complain of a testicular ache.

All suspicious scrotal lumps should be imaged by ultrasound. Serum levels of AFP and β-hCG are elevated in extensive disease. Oestradiol may be elevated, suppressing LH, FSH and testosterone. Accurate staging is based on CT of the lungs, liver and retroperitoneal area.

Management and prognosis
The primary treatment is surgical orchidectomy. Subsequent treatment depends on the histological type and stage. Radiotherapy is the treatment of choice for early-stage seminoma. Teratoma confined to the testes may be managed conservatively, but more advanced cancers are treated with chemotherapy, usually the combination of bleomycin, etoposide and cisplatin. Follow-up is by CT and assessment of AFP and β-hCG. Retroperitoneal lymph node dissection is now performed only for residual or recurrent nodal masses.

The 5-year survival rate for patients with seminoma is 90–95%. For teratomas, the 5-year survival varies between 60% and 95%, depending on tumour type, stage and volume.

Erectile dysfunction
Causes of erectile failure are shown in Box 15.58. Vascular, neuropathic and psychological causes are most common. Exclusion of previously unrecognised cardiovascular disease is important in men presenting with erectile dysfunction. With the exception of diabetes mellitus, endocrine causes are relatively uncommon and are characterised by loss of libido, as well as erectile dysfunction. Erectile dysfunction and reduced libido occur in over 50% of men with advanced CKD or those on dialysis, and is a markedly under-diagnosed problem. It is important to discuss matters frankly with the patient, and to establish whether there are associated features of hypogonadism (p. 655) and if erections occur at any other time. If the patient has erections on waking, vascular and neuropathic causes are much less likely and a psychological cause should be suspected.

Investigations
Blood should be taken for glucose, lipids, thyroid function tests, prolactin, testosterone, LH and FSH. A number of further tests are available but are rarely employed because they do not usually influence management. These include nocturnal tumescence monitoring (using a plethysmograph placed around the shaft of the penis overnight) to establish whether blood supply and nerve function are sufficient to allow erections to occur during sleep; intracavernosal injection of prostaglandin E1 to test the adequacy of blood supply; internal pudendal artery angiography; and tests of autonomic and peripheral sensory nerve conduction.

Management
First-line therapy is usually with oral phosphodiesterase type 5 inhibitors, such as sildenafil, which elevate cyclic guanosine monophosphate (cGMP) levels in vascular smooth muscle cells of the corpus cavernosum, causing vasodilatation and penile erection. Co-administration of these drugs with nitric oxide donors, such as glycerol trinitrate, is contraindicated because of the risk of severe hypotension. Other treatments for impotence include self-administered intracavernosal injection or urethral administration of prostaglandin E1; vacuum devices that achieve an erection maintained by a tourniquet around the base of the penis; and prosthetic implants, either of a fixed rod or an inflatable reservoir. Psychotherapy involving the patient and sexual partner may be helpful for psychological problems. Erectile dysfunction associated with peripheral neuropathy and vascular disease is difficult to treat. If hypogonadism is detected, it should be managed as described on page 655.

Observation

Symptoms and well-being
- Breathlessness
- Distress etc.

Body habitus
- Body mass (obesity, cachexia)
- Marfan’s and other syndromes

Tissue perfusion
- Skin temperature
- Sweating
- Urine output

12 Femoral pulses
    Radio-femoral delay
    Bruits

13 Legs
    Peripheral pulses
    Oedema

4 Examination of the arterial pulse

- The character of the pulse is determined by stroke volume and arterial compliance, and is best assessed by palpating a major artery, such as the carotid or brachial artery.
- Aortic regurgitation, anaemia, sepsis and other causes of a large stroke volume typically produce a bounding pulse with a high amplitude and wide pulse pressure (panel A).
- Aortic stenosis impedes ventricular emptying. If severe, it causes a slow-rising, weak and delayed pulse (panel A).
- Sinus rhythm produces a pulse that is regular in time and force. Arrhythmias may cause irregularity. Atrial fibrillation produces a pulse that is irregular in time and volume (panel B).

5 Examination of the jugular venous pulse

The internal jugular vein, superior vena cava and right atrium are in continuity, so the height of the jugular venous pulsation reflects right atrial pressure. When the patient is placed at 45°, with the head supported and turned to the left, the jugular venous pulse is visible along the line of the sternocleidomastoid muscle (see opposite). In health it is normally just visible above the clavicle.

- The height of the jugular venous pulse is determined by right atrial pressure and is therefore elevated in right heart failure and reduced in hypovolaemia.
- If the jugular venous pulse is not easily seen, it may be exposed by applying firm pressure over the abdomen.
- In sinus rhythm, the two venous peaks, the a and v waves, approximate to atrial and ventricular systole, respectively.
- The x descent reflects atrial relaxation and apical displacement of the tricuspid valve ring. The y descent reflects atrial emptying early in diastole. These signs are subtle.
- Tricuspid regurgitation produces giant v waves that coincide with ventricular systole.

6 Distinguishing venous/arterial pulsation in the neck

- The venous pulse has two peaks in each cardiac cycle; the arterial pulse has one peak.
- The height of the venous pulse varies with respiration (falls on inspiration) and position.
- Abdominal compression causes the venous pulse to rise.
- The venous pulse is not easily palpable and can be occluded with light pressure.

7 Palpation of the precordium

Technique

- Place fingertips over apex (1) to assess for position and character. Place heel of hand over left sternal edge (2) for a parasternal heave or ‘lift’. Assess for thrills in all areas, including the aortic and pulmonary areas (3). Normal position is the 5th or 6th intercostal space, at the mid-clavicular line.

Common abnormalities of the apex beat

- Volume overload, such as mitral or aortic regurgitation: displaced, thrusting
- Pressure overload, such as aortic stenosis, hypertension: discrete, heaving
- Dyskinetic, such as left ventricular aneurysm: displaced, incoordinate

Other abnormalities

- Palpable S1 (tapping apex beat: mitral stenosis)
- Palpable P2 (severe pulmonary hypertension)
- Left parasternal heave or ‘lift’ felt by heel of hand (right ventricular hypertrophy)
- Palpable thrill (aortic stenosis)

8 Auscultation of the heart

- Use the diaphragm to examine at the apex, lower left sternal edge (tricuspid area) and upper left (pulmonary area) and right (aortic area) sternal edges.
- Use the bell to examine low-pitched noises, particularly at the apex for the mid-diastolic murmur of mitral stenosis.
- Time the sounds and murmurs by feeling the carotid pulse; the first heart sound (S1) just precedes the upstroke of the pulse and the second heart sound (S2) is out of step with it. If present, a third heart sound (S3) immediately follows S2, and a fourth heart sound (S4) just precedes S1. Systolic murmurs are synchronous with the pulse.
- Listen for radiation of systolic murmurs, over the base of the neck (aortic stenosis) and in the axilla (mitral incompetence).
- Listen over the left sternal border with the patient sitting forward (aortic incompetence), then at the apex with the patient rolled on to the left side (mitral stenosis).

The haemodynamic effects of respiration are discussed on page 447, and the analysis and interpretation of heart sounds and murmurs on page 457.
Cardiovascular disease is the most frequent cause of adult death in the Western world. In the UK, one-third of men and one-quarter of women will die as a result of ischaemic heart disease. In many developed countries, the incidence of ischaemic heart disease has been falling for the last two or three decades, but it is rising in Eastern Europe and Asia. Cardiovascular disease will soon become the leading cause of death on all continents. Strategies for the treatment and prevention of heart disease can be highly effective and have been subjected to rigorous evaluation. The evidence base for the treatment of cardiovascular disease is stronger than for almost any other disease group.

Valvular heart disease is common but the aetiology varies in different parts of the world. On the Indian subcontinent and in Africa, it is predominantly due to rheumatic fever, whereas calcific aortic valve disease is the most common problem in developed countries.

Prompt recognition of the development of heart disease is limited by two key factors. Firstly, it is often latent; coronary artery disease can proceed to an advanced stage before the patient notices any symptoms. Secondly, the diversity of symptoms attributable to heart disease is limited, so different pathologies may frequently present with the same symptoms.

### Functional anatomy and physiology

**Anatomy**

The heart acts as two serial pumps that share several electrical and mechanical components. The right heart circulates blood to the lungs where it is oxygenated, and the left heart circulates it to the rest of the body (Fig. 16.1). The atria are thin-walled structures that act as priming pumps for the ventricles, which provide most of the energy required to maintain the circulation. The atria are situated posteriorly within the mediastinum where the left atrium (LA) sits anterior to the oesophagus and descending aorta. The right atrium (RA) receives blood from the superior and inferior venae cavae and the coronary sinus. The LA receives blood from four pulmonary veins, two from each of the left and right lungs. The ventricles are thick-walled structures, adapted to circulating blood through large vascular beds under pressure. The atria and ventricles are separated by the annulus fibrosus, which forms the skeleton for the atrioventricular (AV) valves and electrically insulates the atria from the ventricles. The right ventricle (RV) is about 2–3 mm thick and triangular in shape. It extends from the annulus fibrosus to near the cardiac apex and sits anterior to and to the right of the left ventricle (LV). The anterosuperior surface of the RV is rounded and convex, and its posterior extent is bounded by the interventricular septum, which bulges into the chamber. Its upper extent is conical, forming the conus arteriosus or outflow tract, from which the pulmonary artery arises. The LV is more conical in shape and in cross-section is nearly circular. It extends from the LA to the apex of the heart. The LV myocardium is normally around 10 mm thick because it pumps blood at a higher pressure than the RV.

Normally, the heart occupies less than 50% of the transthoracic diameter in the frontal plane, as seen on a chest X-ray. On the patient’s left, the cardiac silhouette is formed by the aortic arch, the pulmonary trunk, the left atrial appendage and the LV. On the right, the silhouette is formed by the RA and the superior and inferior venae cavae, and the lower right border is formed by the RV (Fig. 16.2). In disease states or congenital cardiac abnormalities, the silhouette may change as a result of hypertrophy or dilatation.

### Coronary circulation

The left main and right coronary arteries arise from the left and right sinuses of the aortic root, distal to the aortic valve (Fig. 16.3). Within 2.5 cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (CX), which runs posteriorly in the atrioventricular groove.

![Fig. 16.1 Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mmHg.](image-url)
The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the LV. The CX gives marginal branches that supply the lateral, posterior and inferior segments of the LV. The right coronary artery (RCA) runs in the right atrioventricular groove, giving branches that supply the RA, RV and interposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. This vessel is a branch of the RCA in approximately 90% of people (dominant right system) and is supplied by the CX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many normal variants.

The RCA supplies the sinoatrial (SA) node in about 60% of individuals and the AV node in about 90%. Proximal occlusion of the RCA therefore often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusion of the RCA, due to coronary thrombosis, results in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD or CX causes infarction in the corresponding territory of the LV, and occlusion of the left main coronary artery is usually fatal.

The venous system follows the coronary arteries but drains into the coronary sinus in the atrioventricular groove, and then to the RA. An extensive lymphatic system drains into vessels that travel with the coronary vessels and then into the thoracic duct.

### Conduction system

The SA node is situated at the junction of the superior vena cava and RA (Fig. 16.4). It comprises specialised atrial cells that depolarise at a rate influenced by the autonomic nervous system and by circulating catecholamines. During normal (sinus) rhythm, this depolarisation wave propagates through both atria via sheets of atrial myocytes. The annulus fibrosus forms a conduction barrier between atria and ventricles, and the only pathway through it is the AV node. This is a midline structure, extending from the right side of the interatrial septum, penetrating the annulus fibrosus anteriorly. The AV node conducts relatively slowly, producing a necessary time delay between atrial and ventricular contraction. The His–Purkinje system is composed of the bundle of His extending from the AV node into the interventricular septum, the right and left bundle branches passing along the ventricular septum and into the respective ventricles, the anterior and posterior fascicles of the left bundle branch, and the smaller Purkinje fibres that ramify through the ventricular myocardium. The tissues of the His–Purkinje system conduct very rapidly and allow near-simultaneous depolarisation of the entire ventricular myocardium.

### Nerve supply of the heart

The heart is innervated by both sympathetic and parasympathetic fibres. Adrenergic nerves from the cervical sympathetic chain supply muscle fibres in the atria and ventricles, and the electrical conducting system. Activation of β1-adrenoceptors in the heart results in positive inotropic and chronotropic effects, whereas activation of β2-adrenoceptors in vascular smooth muscle causes vasodilatation. Parasympathetic pre-ganglionic fibres and sensory fibres reach the heart through the vagus nerves. Cholinergic nerves supply the AV and SA nodes via muscarinic (M2) receptors.
Under resting conditions, vagal inhibitory activity predominates and the heart rate is slow. Adrenergic stimulation, associated with exercise, emotional stress, fever and so on, causes the heart rate to increase. In disease states, the nerve supply to the heart may be affected. For example, in heart failure the sympathetic system may be up-regulated, and in diabetes mellitus the nerves themselves may be damaged by autonomic neuropathy (p. 758) so that there is little variation in heart rate.

**Physiology**

### Myocardial contraction

Myocardial cells (myocytes) are about 50–100 μm long; each cell branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction via gap junctions, and mechanical conduction via the fascia adherens, to adjacent cells (Fig. 16.5A). The basic unit of contraction is the sarcomere (2 μm long), which is aligned to those of adjacent myofibrils, giving a striated appearance due to the Z-lines (Fig. 16.5B and C). Actin filaments are attached at right angles to the Z-lines and interdigitate with thicker parallel myosin filaments. The cross-links between actin and myosin molecules contain myofibrillar adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction (Fig. 16.5E). Two chains of actin molecules form a helical structure, with a second molecule, tropomyosin, in the grooves of the actin helix, and a further molecule complex, troponin, attached to every seventh actin molecule (Fig. 16.5D).

During the plateau phase of the action potential, calcium ions enter the cell and are mobilised from the sarcoplasmic reticulum. They bind to troponin and thereby precipitate contraction by shortening of the sarcomere through the interdigitation of the actin and myosin molecules. The force of cardiac muscle contraction, or inotropic state, is regulated by the influx of calcium ions through ‘slow calcium channels’. The extent to which the sarcomere can shorten determines stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or marked exercise. However, the enlargement of the heart seen in heart failure is due to slippage of the myofibrils and adjacent cells rather than lengthening of the sarcomere.

### Cardiac peptides

Cardiomyocytes secrete peptides that have humoral effects on the vasculature and kidneys. Atrial natriuretic peptide (ANP) is a...
28-amino acid peptide, which includes an amino acid ring that acts as a vasodilator, thereby reducing blood pressure (BP), and acts as a diuretic by promoting renal excretion of water and sodium. It is released by atrial myocytes in response to stretch. Brain natriuretic peptide (BNP), which was originally identified in extracts of porcine brain, is a 32-amino acid polypeptide produced by ventricular cardiomyocytes in response to stretch, as occurs in heart failure. Like ANP, it has diuretic properties. Nephrilysin is an enzyme present in the circulation that is produced by the kidney and other tissues. It breaks down ANP, BNP and other proteins and, in so doing, acts as a vasconstrictor. It forms a therapeutic target in patients with heart failure (p. 466).

### Circulation

The RA receives deoxygenated blood from the superior and inferior venae cavae and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood passes through the pulmonary arterial and alveolar capillary bed, where it is oxygenated, then drains through the pulmonary veins into the LA. Blood then passes into the LV, which pumps it into the aorta (see Fig. 16.1). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close, and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close, and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heart beat to the next. Blood passes from the heart through the large central elastic arteries into muscular arteries before encountering the resistance vessels, and ultimately the capillary bed, where there is exchange of nutrients, oxygen and waste products of metabolism. The central arteries, such as the aorta, are predominantly composed of elastic tissue with little or no vascular smooth muscle cells. When blood is ejected from the heart, the compliant aorta expands to accommodate the volume of blood before the elastic recoil sustains BP and flow following cessation of cardiac contraction. This is called the Windkessel effect and it prevents excessive rises in systolic BP while sustaining diastolic BP, thereby reducing cardiac afterload and maintaining coronary perfusion. These benefits are lost with progressive arterial stiffening, which occurs with ageing and advanced renal disease. Passing down the arterial tree, vascular smooth muscle cells progressively play a greater role until the resistance arterioles are encountered. Although all vessels contribute, the resistance vessels (diameter 50–200 μm) provide the greatest contribution to systemic vascular resistance, with small changes in radius having a marked influence on blood flow; resistance is inversely proportional to the fourth power of the radius (Poiseuille’s Law). The tone of these resistance vessels is tightly regulated by humoral, neuronal and mechanical factors. Neurogenic constriction operates via α-adrenoceptors on vascular smooth muscle, and dilatation via muscarinic and β2-adrenoceptors. In addition, systemic and locally released vasoactive substances influence tone; vasoconstrictors include noradrenaline (norepinephrine), angiotensin II and endothelin-1, whereas adenosine, bradykinin, prostaglandins and nitric oxide are vasodilators. Resistance to blood flow rises with viscosity and is mainly influenced by the haematocrit.

Coronary blood vessels receive sympathetic and parasympathetic innervation. While stimulation of α-adrenoceptors causes vasoconstriction and stimulation of β2-adrenoceptors causes vasodilatation, the predominant effect of sympathetic stimulation in coronary arteries is vasodilatation. Parasympathetic stimulation also causes modest dilatation of normal coronary arteries. Because of these homeostatic mechanisms that regulate vessel tone, narrowing or stenosis in a coronary artery does not limit flow, even during exercise, until the cross-sectional area of the vessel is reduced by at least 70%.

### Endothelium

The endothelium plays a vital role in the control of vascular homeostasis. It synthesises and releases many vasoactive mediators that cause vasodilatation, including nitric oxide, prostacyclin and endothelium-derived hyperpolarising factor, and vasoconstriction, including endothelin-1 and angiotensin II. A balance exists whereby the release of such factors contributes to the maintenance and regulation of vascular tone and BP. Damage to the endothelium may disrupt this balance and lead to vascular dysfunction, tissue ischaemia and hypertension.

The endothelium has a major influence on key regulatory steps in the recruitment of inflammatory cells and on the formation and dissolution of thrombus. Once activated, the endothelium expresses surface receptors such as E-selectin, intercellular adhesion molecule type 1 (ICAM-1) and platelet-endothelial cell adhesion molecule type 1 (PECAM-1), which mediate rolling, adhesion and migration of inflammatory leucocytes into the subintima. The endothelium also stores and releases the multimeric glycoprotein von Willebrand factor, which promotes thrombus formation by linking platelet adhesion to denuded surfaces, especially in the arterial vasculature. In contrast, once intravascular thrombi forms, tissue plasminogen activator is rapidly released from a dynamic storage pool within the endothelium to induce fibrinolysis and thrombus dissolution. These processes are critically involved in the development and progression of atherosclerosis, and endothelial function and injury are seen as central to the pathogenesis of many cardiovascular disease states.

### Respiration

Cardiac output, BP and pulse rate change with respiration as the result of changes in blood flow to the right and left heart, as summarised in Box 16.1. During inspiration the fall in intrathoracic pressure causes increased return of venous blood into the chest and right side of the heart, which increases cardiac output from the RV. A substantial amount of blood is sequestered in the lungs, however, due to increased capacitance of the pulmonary vascular bed, which causes a reduction in blood flow to the left side of the heart. This causes a reduction in cardiac output from the LV and a slight fall in BP. With expiration the opposite sequence of events occurs; there is a fall in venous return to the right heart with a reduction in RV output, and a rise in the venous return to the left side of the heart with an increase in LV output. As the result of these changes, BP normally falls during inspiration.

*Inspiration prolongs right ventricular ejection, delaying P2, and shortens left ventricular ejection, bringing forward A2; expiration produces the opposite effects.
but rises during expiration. These changes are exaggerated in patients with severe airways obstruction secondary to asthma or chronic obstructive pulmonary disease (COPD) leading to pulsatilis paradoxus, which describes an exaggerated fall in BP during inspiration. As well as being found in airways obstruction, pulsatilis paradoxus is also characteristic of cardiac tamponade (p. 544). Here, cardiac filling is constrained by external pressure, and on inspiration compression of the RV impedes the normal increase in flow through it on inspiration. The interventricular septum then moves to the left, impeding left ventricular filling and cardiac output. This produces a marked fall in BP (>10 mmHg fall during inspiration).

**Investigation of cardiovascular disease**

Several investigations may be required in the diagnosis of cardiac disease and assessment of its severity. Basic tests, such as electrocardiography, chest X-ray and echocardiography, can be performed in an outpatient clinic or at the bedside, whereas more complex procedures such as cardiac catheterisation, radionuclide imaging, computed tomography (CT) and magnetic resonance imaging (MRI) require specialised facilities.

**Electrocardiogram**

The electrocardiogram (ECG) is used to assess cardiac rhythm and conduction, and is the main test used in the diagnosis of myocardial ischaemia and infarction.

The physiological basis of an ECG recording is the fact that electrical depolarisation of myocardial tissue produces a small dipole current, which can be detected by electrode pairs on the body surface. These signals are amplified and either printed or displayed on a monitor (Fig. 16.6). During sinus rhythm, the SA node triggers atrial depolarisation, producing a P wave. Depolarisation proceeds slowly through the AV node, which is too small to produce a depolarisation wave detectable from the body surface. The bundle of His, bundle branches and Purkinje system are then activated, initiating ventricular myocardial depolarisation, which produces the QRS complex. The muscle mass of the ventricles is much larger than that of the atria, so the QRS complex is larger than the P wave. The interval between the onset of the P wave and the onset of the QRS complex is termed the ‘PR interval’ and largely reflects the duration of AV nodal conduction. Injury to the left or right bundle branch delays ventricular depolarisation, widening the QRS complex. Selective injury of one of the left fascicles (hemiblock, p. 479) affects the electrical axis. Repolarisation is slower and spreads from the epicardium to the endocardium. Atrial repolarisation does not cause a detectable signal but ventricular repolarisation produces the T wave. The QT interval represents the total duration of ventricular depolarisation and repolarisation.

**The 12-lead ECG**

The 12-lead ECG (Box 16.2) is generated from 10 electrodes that are attached to the skin. One electrode is attached to each limb and six electrodes are attached to the chest. In addition, the left arm, right arm and left leg electrodes are attached to a central terminal acting as an additional virtual electrode in the centre of the chest (the right leg electrode acts as an earthing electrode). The 12 ‘leads’ of the ECG refer to recordings made from pairs or sets of these electrodes. They comprise three groups: three dipole limb leads, three augmented voltage limb leads and six unipole chest leads.

Leads I, II and III are the dipole limb leads and refer to recordings obtained from pairs of limb electrodes. Lead I records depolarisation towards electrode:

**QRS complex: ventricular depolarisation**

- R

**P wave: atrial depolarisation**

**T wave: ventricular repolarisation**

**P wave (0.12 sec)**

**QRS width (0.10 sec)**

**PR interval (0.20 sec)**

**QT interval (0.42 sec at rate of 60/min)**

**Fig. 16.6 The electrocardiogram.** The components correspond to depolarisation and repolarisation, as depicted in Figure 16.4. The upper limit of the normal range for each interval is given in brackets.
the signal between the right (negative) and left (positive) arms. Lead II records the signal between the right arm (negative) and left leg (positive). Lead III records the signal between the left arm (negative) and left leg (positive). These three leads thus record electrical activity along three different axes in the frontal plane. Leads aVR, aVL, and aVF are the augmented voltage limb leads. These record electrical activity between a limb electrode and a modified central terminal. For example, lead aVL records the signal between the left arm (positive) and central (negative) terminal, formed by connecting the right arm and left leg electrodes (Fig. 16.7). Similarly augmented signals are obtained from the right arm (aVR) and left leg (aVF). These leads also record electrical activity in the frontal plane, with each lead 120° apart. Lead aVF thus examines activity along the axis +90°, and lead aVL along the axis −30°, and so on.

When depolarisation moves towards a positive electrode, it produces a positive deflection in the ECG; depolarisation in the opposite direction produces a negative deflection. The average vector of ventricular depolarisation is known as the frontal cardiac axis. When the vector is at right angles to a lead, the depolarisation in that lead is equally negative and positive (isoelectric). In Figure 16.7A, the QRS complex is isoelectric in aVL, negative in aVR and most strongly positive in lead II; the main vector or axis of depolarisation is therefore 60°. The normal cardiac axis lies between −30° and +90°. Examples of left and right axis deviation are shown in Figures 16.7B and C.

There are six chest leads, V1–V6, derived from electrodes placed on the anterior and lateral left side of the chest, over the heart. Each lead records the signal between the corresponding chest electrode (positive) and the central terminal (negative). Leads V1 and V2 lie approximately over the RV, V3 and V4 over the interventricular septum, and V5 and V6 over the LV (Fig. 16.8). The LV has the greater muscle mass and contributes the major component of the QRS complex.

The shape of the QRS complex varies across the chest leads. Depolarisation of the interventricular septum occurs first and moves from left to right; this generates a small initial negative deflection in lead V6 (Q wave) and an initial positive deflection in lead V1 (R wave). The second phase of depolarisation is activation of the body of the LV, which creates a large positive deflection or R wave in V6 (with reciprocal changes in V1). The third and final phase involves the RV and produces a small negative deflection or S wave in V6.

**Exercise ECG**

In exercise or stress electrocardiography a 12-lead ECG is recorded during exercise on a treadmill or bicycle ergometer. It is similar to a resting ECG, except that the limb electrodes are placed on the shoulders and hips rather than the wrists and ankles. The Bruce Protocol is the most commonly used. During an exercise ECG, BP is recorded and symptoms are assessed. Common indications for exercise testing are shown in Box 16.3. The test is considered positive if angina occurs, BP falls or fails to increase, or if there are ST segment shifts of more than 1 mm (see Fig. 16.57, p. 490). Exercise testing is useful in confirming the diagnosis of coronary artery disease in patients with suspected angina, and under these circumstances has good sensitivity and specificity (Box 16.3). False-negative
results can, however, occur in patients with coronary artery disease, and not all patients with a positive test have coronary disease. This is especially true in low-risk individuals, such as asymptomatic young or middle-aged women, in whom an abnormal response is more likely to represent a false-positive than a true-positive test. Stress testing is contraindicated in the presence of acute coronary syndrome, decompensated heart failure and severe hypertensive.

### Ambulatory ECG

Ambulatory ECG recordings can be obtained using a portable digital recorder. These devices usually provide limb lead ECG recordings only, on a continuous basis for periods of between 1 and 7 days. The main indication for ambulatory ECG is in the investigation of patients with suspected arrhythmia, such as those with intermittent palpitation, dizziness or syncope. In this situation a standard ECG provides only a snapshot of the cardiac rhythm and is unlikely to detect an intermittent arrhythmia, so a longer period of recording is required (see Fig. 16.32, p. 469). Ambulatory ECG can also be used to assess rate control in patients with atrial fibrillation, and to detect transient myocardial ischaemia using ST segment analysis. If symptoms are infrequent, special recorders can be issued that can be activated by the patient using ST segment analysis. If symptoms are infrequent, special recorders can be issued that can be activated by the patient.

### Cardiac biomarkers

Several biomarkers are available that can be measured in peripheral blood to assess myocardial dysfunction and ischaemia.

### Brain natriuretic peptide

Brain natriuretic peptide (BNP) is a peptide hormone of 32 amino acids with diuretic properties. It is secreted by the LV as a 108-amino acid prohormone, which is cleaved to produce active BNP, and an inactive 76-amino acid N-terminal fragment (NT-proBNP). Circulating levels are elevated in conditions associated with LV systolic dysfunction. Generally, NT-proBNP is measured in preference to BNP since it has a longer half-life. Measurements of NT-proBNP are indicated for the diagnosis of LV dysfunction and to assess prognosis and response to therapy in patients with heart failure (p. 461).

### Cardiac troponins

Troponin I and troponin T are structural cardiac muscle proteins (see Fig. 16.5) that are released during myocyte damage and necrosis, and represent the cornerstone of the diagnosis of acute myocardial infarction (MI, Box 16.47, p. 493). Modern assays are extremely sensitive, however, and can detect minor degrees of myocardial damage, so that elevated plasma troponin concentrations may be observed in conditions other than acute MI, such as pulmonary embolus, septic shock and pulmonary oedema.

### Chest X-ray

This is useful for determining the size and shape of the heart, and the state of the pulmonary blood vessels and lung fields. Most information is given by a postero-anterior (PA) projection taken in full inspiration. Anteroposterior (AP) projections can be performed when patient movement is restricted but result in magnification of the cardiac shadow.

An estimate of overall heart size can be made by comparing the maximum width of the cardiac outline with the maximum internal transverse diameter of the thoracic cavity. The term cardiomegaly is used to describe an enlarged cardiac silhouette when the ratio of cardiac width to the width of the lung fields is greater than 0.5. Cardiomegaly can be caused by chamber dilatation, especially left ventricular dilatation, or by a pericardial effusion, but may also be due to a mediastinal mass or pectus excavatum (p. 628). Cardiomegaly is not a sensitive indicator of left ventricular systolic dysfunction since the cardiothoracic ratio is normal in many patients with poor left ventricular function and is not specific, since many patients with cardiomegaly on chest X-ray have normal echocardiograms.

Dilatation of individual cardiac chambers can be recognised by the characteristic alterations to the cardiac silhouette (Fig. 16.9):

- Left atrial dilatation results in prominence of the left atrial appendage, creating the appearance of a straight left heart border, a double cardiac shadow to the right of the sternum, and widening of the angle of the carina (bifurcation of the trachea) as the left main bronchus is pushed upwards.
- Right atrial enlargement projects from the right heart border towards the right lower lung field.
- Left ventricular dilatation causes prominence of the left heart border and enlargement of the cardiac silhouette. Left ventricular hypertrophy produces rounding of the left heart border (Fig. 16.10).
- Right ventricular dilatation increases heart size, displaces the apex upwards and straightens the left heart border.

Lateral or oblique projections may be useful for detecting pericardial calcification in patients with constrictive pericarditis (p. 543) or a calcified thoracic aortic aneurysm, as these abnormalities may be obscured by the spine on the PA view.

The lung fields on the chest X-ray may show congestion and oedema in patients with heart failure (see Fig. 16.27, p. 464), and an increase in pulmonary blood flow (‘pulmonary plethora’) in those with left-to-right shunt. Pleural effusions may also occur in heart failure.
**Investigation of cardiovascular disease**

**Doppler echocardiography**

Doppler echocardiography provides information on blood flow within the heart and the great vessels. It is based on the Doppler principle that sound waves reflected from moving objects, such as red blood cells, undergo a frequency shift. Doppler echocardiography can therefore detect the speed and direction of blood flow in the heart chambers and great vessels. The greater the frequency shift, the faster the blood is moving. The information can be presented either as a plot of blood velocity against time for a particular point in the heart (Fig. 16.11) or as...
Stress echocardiography

Stress echocardiography is used to investigate patients with suspected coronary artery disease who are unsuitable for exercise stress testing, such as those with mobility problems or pre-existing bundle branch block. A two-dimensional echo is performed before and after infusion of a moderate to high dose of an inotrope, such as dobutamine. Myocardial segments with poor perfusion become ischaemic and contract poorly under stress, manifesting as a wall motion abnormality on the scan. Stress echocardiography is sometimes used to examine myocardial viability in patients with impaired left ventricular function. Low-dose dobutamine can induce contraction in ‘hibernating’ myocardium; such patients may benefit from bypass surgery or percutaneous coronary intervention.

Computed tomography

Computed tomography (CT) is useful for imaging the cardiac chambers, great vessels, pericardium, and mediastinal structures and masses. Multidetector scanners can acquire up to 320 slices per rotation, allowing very high-resolution imaging in a single heart beat. CT is often performed using a timed injection of X-ray contrast to produce clear images of blood vessels and associated pathologies. Contrast scans are very useful for imaging the aorta in suspected aortic dissection (see Fig. 16.74, p. 507), and the pulmonary arteries and branches in suspected pulmonary embolism (p. 619).

Some centres use cardiac CT scans for quantification of coronary artery calcification, which may serve as an index of cardiovascular risk. However, modern multidetector scanning allows non-invasive coronary angiography (Fig. 16.13) with a spatial resolution approaching that of conventional coronary arteriography and at a lower radiation dose. CT coronary angiography is particularly useful in the initial assessment of patients with chest pain and a low or intermediate likelihood of disease, since it has a high negative predictive value in excluding coronary artery disease. Modern volume scanners are also able to assess myocardial perfusion, often at the same sitting.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can be used to generate cross-sectional images of the heart, lungs and mediastinal structures. It provides better differentiation of soft tissue structures than CT
help in selecting patients for revascularisation procedures, or in
identifying those with myocardial infiltration, such as that seen
with sarcoid heart disease and arrhythmogenic right ventricular
cardiomyopathy.

**Cardiac catheterisation**

This involves passing a specialised catheter through a peripheral
vein or artery into the heart under X-ray guidance. Cardiac
catheterisation allows BP and oxygen saturation to be measured
in the cardiac chambers and great vessels, and is used to
perform angiograms by injecting contrast media into a chamber
or blood vessel.

Left heart catheterisation involves accessing the arterial
circulation, usually through the radial artery, to allow catheterisation
of the aorta, LV and coronary arteries. Coronary angiography
is the most widely performed procedure, in which the left
and right coronary arteries are selectively imaged, providing
information about the extent and severity of coronary stenoses,
thrombus and calcification (Fig. 16.15). Additional anatomical
but is poor at demonstrating calcification. MRI scans need to
be ‘gated’ to the ECG, allowing the scanner to produce moving
images of the heart and mediastinal structures throughout the
cardiac cycle. MRI is very useful for imaging the aorta, including
suspected dissection (see Fig. 16.73, p. 507), and can define
the anatomy of the heart and great vessels in patients with
congenital heart disease. It is also useful for detecting infiltrative
conditions affecting the heart and for evaluation of the RV that
is difficult to image by echocardiography.

Physiological data can be obtained from the signal returned
from moving blood, which allows quantification of blood flow
across regurgitant or stenotic valves. It is also possible to analyse
regional wall motion in patients with suspected coronary disease
or cardiomyopathy.

Myocardial perfusion and viability can also be readily assessed
by MRI. When enhanced by gadolinium-based contrast media,
areas of myocardial hypoperfusion can be identified with better
spatial resolution than nuclear medicine techniques. Later
redistribution of this contrast, so-called delayed enhancement,
can be used to identify myocardial scarring and fibrosis: this
is a particular strength of cardiac MRI (Fig. 16.14). This can

Presenting problems in cardiovascular disease

Cardiovascular disease gives rise to a relatively limited range of symptoms. Making the correct diagnosis depends on careful analysis of the factors that provoke symptoms, the subtle differences in how they are described by the patient, the clinical findings and the results of investigations. A close relationship between symptoms and exercise is the hallmark of heart disease. The New York Heart Association (NYHA) functional classification is used to grade disability (Box 16.5).

Chest pain on exertion

There are many other non-cardiac causes of chest pain, as discussed in Chapter 10. This section will focus on exertional chest pain, which is a typical presenting symptom of coronary artery disease.

Clinical assessment

A careful history is crucial in determining whether chest pain is cardiac or not. Chest pain on effort is the hallmark of angina pectoris (Fig. 16.16). The reproducibility, predictability and relationship to physical exertion (and occasionally emotion) of the chest pain are the most important features. The duration of symptoms should be noted because patients with recent-onset angina are at greater risk than those with long-standing and unchanged symptoms. Physical examination is often normal but

Electrophysiology

Patients with known or suspected arrhythmia are investigated by percutaneous placement of electrode catheters into the heart via the femoral and neck veins. An electrophysiology study (EPS) is most commonly performed to evaluate patients for catheter ablation and is normally done at the same time as the ablation procedure. EPS is occasionally used for risk stratification of patients suspected of being at risk of ventricular arrhythmias.

Radionuclide imaging

Radionuclide imaging can be used to evaluate cardiac function but is declining in popularity due to the availability of MRI, which does not involve exposure to radiation and provides equivalent or superior quality data to radionuclide imaging.

Blood pool imaging

The patient is given an intravenous injection of radioisotope-labelled blood cells, and after 4–5 minutes the distribution of isotope in the heart is evaluated by a gamma camera at different phases of the cardiac cycle, thereby permitting the calculation of ventricular ejection fractions. It also allows the assessment of the size and ‘shape’ of the cardiac chambers.

Myocardial perfusion scanning

The patient is given an intravenous injection of a radioactive isotope, such as $^{99}$technetium tetrofosmin, and scintiscans of the myocardium are subsequently obtained by gamma camera at rest and during stress (see Fig. 16.58, p. 490). Either exercise stress or pharmacological stress (using the inotrope dobutamine or the vasodilator dipyridamole) can be used. More sophisticated quantitative information can be obtained with positron emission tomography (PET), which can also be used to assess myocardial metabolism, but this is available in only a few centres.

![Fig. 16.16 Typical ischaemic cardiac pain. Characteristic hand gestures used to describe cardiac pain. Typical radiation of pain is shown in the schematic.](image-url)
may reveal evidence of risk factors for cardiovascular disease, such as xanthoma or xanthelasma indicating hyperlipidaemia (p. 373). Signs of anaemia (p. 923) or thyrotoxicosis (p. 635) may be identified, both of which can exacerbate angina. Cardiovascular examination may reveal evidence of left ventricular dysfunction (p. 442) or cardiac murmurs in patients with aortic valve disease and hypertrophic cardiomyopathy. Other manifestations of arterial disease, such as bruits and loss of peripheral pulses, may also be observed.

**Investigations**

A full blood count, fasting blood glucose, lipids, thyroid function tests and a 12-lead ECG are the most important baseline investigations. An exercise ECG is helpful in identifying high-risk patients who require further investigation and treatment but cannot reliably exclude the presence of coronary artery disease (p. 449). In patients with chest pain where the exercise ECG is normal but where there is a suspicion of coronary artery disease, CT coronary angiography should be performed. If a murmur is found, echocardiography should be performed to check for valve disease or hypertrophic cardiomyopathy.

### Severe prolonged chest pain

Severe prolonged cardiac chest pain may be due to acute myocardial infarction or to unstable angina (p. 493). These are known collectively as the acute coronary syndromes.

**Clinical assessment**

Acute coronary syndrome is suggested by a previous history of stable angina but an episode of acute severe chest pain at rest can be the first presentation of coronary artery disease. Making the correct diagnosis depends on analysing the character of the pain and its associated features. Physical examination may reveal signs of risk factors for coronary artery disease as described for exertional chest pain, and pallor or sweating, which is indicative of autonomic disturbance and typical of acute coronary syndrome. Other features, such as arrhythmia, hypotension and heart failure, may occur. Patients presenting with symptoms consistent with an acute coronary syndrome require admission to hospital and urgent investigation because there is a high risk of avoidable complications.

**Investigations**

A 12-lead ECG is mandatory and is the most useful method of initial triage, along with measurement of serum troponin I or T. The diagnosis of an acute coronary syndrome is supported by ST segment elevation or depression on ECG and an elevated level of troponin I or T, which demonstrates that there has been myocardial damage.

If the diagnosis remains unclear after initial investigation, repeat ECG recordings should be performed and are particularly useful if they can be obtained during an episode of pain. If the plasma troponin concentrations are normal at baseline, repeat measurements should be made 6–12 hours after the onset of symptoms or admission to hospital. New ECG changes or an elevated plasma troponin concentration confirm the diagnosis of an acute coronary syndrome. If the pain settles and does not recur, there are no new ECG changes and troponin concentrations remain normal, the patient can be discharged from hospital but further investigations may be indicated to look for evidence of coronary artery disease, as discussed on page 484.

### Management

The differential diagnosis and management of acute coronary syndrome are described in more detail on pages 494 and 498.

### Breathlessness

Cardiac causes of breathlessness include cardiac arrhythmias, acute and chronic heart failure, acute coronary syndrome, valvular disease, cardiomyopathy and constrictive pericarditis, all discussed later in this chapter. The differential diagnosis of breathlessness is wide, however, and has many other non-cardiac causes. These are discussed in more detail on pages 179 and 557.

### Syncope

The term ‘syncope’ refers to loss of consciousness due to reduced cerebral perfusion. The differential diagnosis, investigation and management of syncope are discussed on page 181.

### Palpitation

Palpitation is a common and sometimes frightening symptom that is usually due to a disorder of cardiac rhythm. Patients use the term to describe many sensations, including an unusually erratic, fast, slow or forceful heart beat, or even chest pain or breathlessness.

**Clinical assessment**

Initial evaluation should concentrate on determining the likely mechanism of palpitation and whether or not there is significant underlying heart disease. A detailed description of the sensation is essential and patients should be asked to describe their symptoms clearly, or to demonstrate the sensation of rhythm by tapping with their hand. A provisional diagnosis can usually be made on the basis of a thorough history (Box 16.6 and Fig. 16.17). Recurrent but short-lived bouts of an irregular heart beat are usually due to atrial or ventricular extrasystoles (ectopic beats). Some patients will describe the experience as a ‘flip’ or a ‘jolt’ in the chest, while others report dropped or missed beats. Extrasystoles are often more frequent during periods of stress or debility; they can be triggered by alcohol or nicotine.

Episodes of a pounding, forceful and relatively fast (90–120/min) heart beat are a common manifestation of anxiety. These may also reflect a hyperdynamic circulation, such as anaemia, pregnancy and thyrotoxicosis, and can occur in some forms of valve disease such as aortic regurgitation. Discrete bouts of a
Cardiac arrest describes the sudden and complete loss of cardiac output due to asystole, ventricular tachycardia or fibrillation, or loss of mechanical cardiac contraction (pulseless electrical activity). The clinical diagnosis is based on the victim being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable, unless effective treatment is given promptly. Sudden cardiac death is usually caused by a catastrophic arrhythmia and accounts for 25–30% of deaths from cardiovascular disease, claiming an estimated 70,000 to 90,000 lives each year in the UK. Many of these deaths are potentially preventable.

Pathogenesis

Coronary artery disease is the most common cause of cardiac arrest. Ventricular fibrillation or ventricular tachycardia is common in the first few hours of MI and many victims die before medical help is sought. Up to one-third of people developing MI die before reaching hospital, emphasising the importance of educating the public to recognise symptoms and to seek medical help quickly. Acute myocardial ischaemia in the absence of infarction can also cause these arrhythmias, but less commonly. Patients with a history of previous MI are at increased risk of sudden arrhythmic death, especially if there is extensive left ventricular scarring and impairment, or if there is ongoing myocardial ischaemia. Cardiac arrest may be caused by ventricular fibrillation (Fig. 16.18), pulseless ventricular tachycardia (p. 457), asystole or pulseless electrical activity. These can complicate many types of heart disease, including cardiomyopathies, and sometimes can occur in the absence of recognised structural abnormalities. The causes are listed in Box 16.7. Sudden death less often occurs because of an acute mechanical catastrophe such as cardiac rupture or aortic dissection (pp. 496 and 506).

Clinical assessment and management

Basic life support

When a patient with suspected cardiac arrest is encountered, the ABCDE approach to management should be followed; this involves prompt assessment and restoration of the Airway, maintenance of ventilation using rescue Breathing ('mouth-to-mouth' breathing), and maintenance of the Circulation using chest compressions; Disability, in resuscitated patients, refers to assessment of neurological status, and Exposure entails removal of clothes to enable defibrillation, auscultation of the chest, and assessment for a rash caused by anaphylaxis, for injuries and so on (Fig. 16.19). The term basic life support (BLS)

Advanced life support

Advanced life support (ALS) (Fig. 16.20) aims to restore normal cardiac rhythm by defibrillation when the cause of cardiac arrest is a tachyarrhythmia, or to restore cardiac output by correcting other reversible causes of cardiac arrest. The initial priority is to assess the patient’s cardiac rhythm by attaching a defibrillator or monitor. Once that this has been done, treatment should be instituted based on the clinical findings.

Ventricular fibrillation or pulseless ventricular tachycardia should be treated with immediate defibrillation. Defibrillation is more likely to be effective if a biphasic shock defibrillator is used, where the polarity of the shock is reversed midway through its delivery. Defibrillation is usually administered using a 150-joule biphasic shock, and CPR resumed immediately for 2 minutes without attempting to confirm restoration of a pulse because restoration of mechanical cardiac output rarely occurs immediately after successful defibrillation. If, after 2 minutes, a pulse is not restored, a further biphasic shock of 150–200 joules should be given. Thereafter, additional biphasic shocks of 150–200 joules are given every 2 minutes after each cycle of CPR. During resuscitation, adrenaline (epinephrine, 1 mg IV) should be given every 3–5 minutes and consideration given to the use of intravenous amiodarone, especially if ventricular fibrillation or ventricular tachycardia re-initiates after successful defibrillation.

Ventricular fibrillation of low amplitude, or ‘fine VF’, may mimic asystole. If asystole cannot be confidently diagnosed, the patient should be treated for VF and defibrillated. If an electrical rhythm is observed that would be expected to produce a cardiac output, ‘pulseless electrical activity’ is present. Pulseless electrical activity should be treated by continuing CPR and adrenaline (epinephrine) administration while seeking such causes. Asystole should be treated similarly, with the additional support of atropine and sometimes external or transvenous pacing in an attempt to generate an electrical rhythm. There are many potentially reversible causes of cardiac arrest; the main ones can be easily remembered as a list of four Hs and four Ts (Fig. 16.20).

The Chain of Survival

This term refers to the sequence of events that is necessary to maximise the chances of a cardiac arrest victim surviving (Fig. 16.21). Survival is most likely if all links in the chain are strong: that is, if the arrest is witnessed, help is called immediately, basic life support is administered by a trained individual, the emergency medical services respond promptly, and defibrillation is achieved within a few minutes. Good training in both basic and advanced life support is essential and should be maintained by regular refresher courses. In recent years, public access defibrillation has been introduced in places of high population density, particularly where traffic congestion may impede the response of emergency services, such as railway stations, airports and sports stadia. Designated individuals can respond to a cardiac arrest using BLS and an automated external defibrillator.

Survivors of cardiac arrest

Patients who survive a cardiac arrest caused by acute MI need no specific treatment beyond that given to those recovering from an uncomplicated infarct, since their prognosis is similar (p. 498). Those with reversible causes, such as exercise-induced ischaemia or aortic stenosis, should have the underlying cause treated if possible. Survivors of ventricular tachycardia or ventricular fibrillation arrest in whom no reversible cause can be identified may be at risk of another episode, and should be considered for an implantable cardiac defibrillator (p. 483) and anti-arrhythmic drug therapy. In these patients, the risk is reduced by treatment of heart failure with β-adrenoceptor antagonists (β-blockers) and angiotensin-converting enzyme (ACE) inhibitors, and by coronary revascularisation.

Abnormal heart sounds

The first indication of heart disease may be the discovery of an abnormal sound on auscultation (Box 16.8). This may be incidental – for example, during a routine childhood examination – or may be prompted by symptoms of heart disease.

Clinical assessment

The aims of clinical assessment are, firstly, to determine if the abnormal sound is cardiac; secondly, to determine if it is pathological; and thirdly, to try to determine its cause.

Is the sound cardiac?

Additional heart sounds and murmurs demonstrate a consistent relationship to a specific part of the cardiac cycle, whereas extracardiac sounds, such as a pleural rub or venous hum,

Fig. 16.21 The Chain of Survival in cardiac arrest. (ALS = advanced life support; CPR = cardiopulmonary resuscitation)
Pathological sounds and murmurs are the product of turbulent blood flow or rapid ventricular filling due to abnormal loading conditions. Some added sounds are physiological but may also occur in pathological conditions; for example, a third sound is common in young people and in pregnancy but is also a feature of heart failure (Box 16.8). Similarly, a systolic murmur due to turbulence across the right ventricular outflow tract may occur in hyperdynamic states such as anaemia or pregnancy, but may also be due to pulmonary stenosis or an intracardiac shunt leading to volume overload of the RV, such as an atrial septal defect. Benign murmurs do not occur in diastole (Box 16.9), and systolic murmurs that radiate or are associated with a thrill are almost always pathological.

What is the origin of the sound?
Timing, intensity, location, radiation and quality are all useful clues to the origin and nature of an additional sound or murmur (Box 16.10). Radiation of a murmur is determined by the direction of turbulent blood flow and is detectable only when there is a high-velocity jet, such as in mitral regurgitation (radiation from apex to axilla) or aortic stenosis (radiation from base to neck). Similarly, the pitch and quality of the sound can help to distinguish the murmur, such as the ‘blowing’ murmur of mitral regurgitation or the ‘rasping’ murmur of aortic stenosis. The position of a murmur in relation to the cardiac cycle is crucial and should be assessed by timing it with the heart sounds, carotid pulse and apex beat (Figs 16.22 and 16.23).

Systolic murmurs
Ejection systolic murmurs are associated with ventricular outflow tract obstruction and occur in mid-systole with a

Diastolic murmurs

These are due to accelerated or turbulent flow across the mitral or tricuspid valves. They are low-pitched noises that are often difficult to hear and should be evaluated with the bell of the stethoscope.

- A mid-diastolic murmur may be due to mitral stenosis (located at the apex and axilla), tricuspid stenosis (located at the left sternal edge), increased flow across the mitral valve (for example, the to-and-fro murmur of severe mitral regurgitation) or increased flow across the tricuspid valve (for example, a left-to-right shunt through a large atrial septal defect). Early diastolic murmurs have a soft, blowing quality with a decrescendo pattern and should be evaluated with the diaphragm of the stethoscope. They are due to regurgitation across the aortic or pulmonary valves and are best heard at the left sternal edge, with the patient sitting forward in held expiration.

**Fig. 16.23** The timing and pattern of cardiac murmurs.
Continuous murmurs
These result from a combination of systolic and diastolic flow, such as occurs with a persistent ductus arteriosus, and must be distinguished from extracardiac noises such as bruits from arterial shunts, venous hums (high rates of venous flow in children) and pericardial friction rubs.

Investigations
If clinical evaluation suggests that the additional sound is cardiac and likely to be pathological, then echocardiography is indicated to determine the underlying cause.

Management
Management of patients with additional cardiac sounds depends on the underlying cause. More details are provided in the sections on specific valve defects and congenital anomalies later in this chapter (pp. 514 and 531).

Heart failure
Heart failure describes the clinical syndrome that develops when the heart cannot maintain adequate output, or can do so only at the expense of elevated ventricular filling pressure. In mild to moderate forms of heart failure, symptoms occur only when the metabolic demand increases during exercise or some other form of stress. In severe heart failure, symptoms may be present at rest. In clinical practice, heart failure may be diagnosed when a patient with significant heart disease develops the signs or symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion at rest or on exercise. Three types of heart failure are recognised.

Left heart failure
This is characterised by a reduction in left ventricular output and an increase in left atrial and pulmonary venous pressure. If left heart failure occurs suddenly – for example, as the result of an acute MI – the rapid increase in left atrial pressure causes pulmonary oedema. If the rise in atrial pressure is more gradual, as occurs with mitral stenosis, there is reflex pulmonary vasoconstriction, which protects the patient from pulmonary oedema. However, the resulting increase in pulmonary vascular resistance causes pulmonary hypertension, which in turn impairs right ventricular function.

Right heart failure
This is characterised by a reduction in right ventricular output and an increase in right atrial and systemic venous pressure. The most common causes are chronic lung disease, pulmonary embolism and pulmonary valvular stenosis. The term ‘cor pulmonale’ is used to describe right heart failure that is secondary to chronic lung disease.

Biventricular heart failure
In biventricular failure, both sides of the heart are affected. This may occur because the disease process, such as dilated cardiomyopathy or ischaemic heart disease, affects both ventricles or because disease of the left heart leads to chronic elevation of the left atrial pressure, pulmonary hypertension and right heart failure.

Epidemiology
Heart failure predominantly affects the elderly; the prevalence rises from 1% in those aged 50–59 years to over 10% in those aged 80–89 years. In the UK, most patients admitted to hospital with heart failure are more than 70 years old; they typically remain hospitalised for a week or more and may be left with chronic disability. Although the outlook depends, to some extent, on the underlying cause of the problem, untreated heart failure generally carries a poor prognosis; approximately 50% of patients with severe heart failure due to left ventricular dysfunction will die within 2 years because of either pump failure or malignant ventricular arrhythmias. The most common causes are coronary artery disease and myocardial infarction but almost all forms of heart disease can lead to heart failure, as summarised in Box 16.12. An accurate diagnosis is important because treatment of the underlying cause may reverse heart failure or prevent its progression.

Pathogenesis
Heart failure occurs when cardiac output fails to meet the demands of the circulation. Cardiac output is determined by preload (the volume and pressure of blood in the ventricles at the end of diastole), afterload (the volume and pressure of blood in the ventricles during systole) and myocardial contractility, forming the basis of Starling’s Law (Fig. 16.24). The causes of heart failure are discussed below.

Ventricular dysfunction
Ventricular dysfunction is the most common cause of heart failure. This can occur because of impaired systolic contraction due to myocardial disease, or diastolic dysfunction where there is abnormal ventricular relaxation due to a stiff, non-compliant ventricle. This is most commonly found in patients with left ventricular hypertrophy. Systolic dysfunction and diastolic dysfunction often coexist, particularly in patients with coronary artery disease. Ventricular dysfunction reduces cardiac output, which, in turn, activates the sympathetic nervous system (SNS) and renin–angiotensin–aldosterone system (RAAS). Under normal circumstances, activation of the SNS and RAAS supports cardiac function but, in the setting of impaired ventricular function, the consequences are negative and lead to an increase in both afterload and preload (Fig. 16.25). A vicious circle may then be

**Fig. 16.25 Neurohumoral activation and compensatory mechanisms in heart failure.** There is a vicious circle in progressive heart failure.

Established because any additional fall in cardiac output causes further activation of the SNS and RAAS, and an additional increase in peripheral vascular resistance. Activation of the RAAS causes vasoconstriction and sodium and water retention. This is primarily mediated by angiotensin II, a potent constrictor of arterioles, in both the kidney and the systemic circulation (Fig. 16.25). Activation of the SNS also occurs and can initially sustain cardiac output through increased myocardial contractility and heart rate. Prolonged sympathetic stimulation has negative effects, however, causing cardiac myocyte apoptosis, cardiac hypertrophy and focal myocardial necrosis. Sympathetic stimulation also contributes to vasoconstriction and predisposes to arrhythmias. Sodium and water retention is further enhanced by the release of aldosterone, endothelin-1 (a potent vasoconstrictor peptide with marked effects on the renal vasculature) and, in severe heart failure, vasopressin (antidiuretic hormone, ADH). Natriuretic peptides are released from the atria in response to atrial dilatation and compensate to an extent for the sodium-conserving effect of aldosterone, but this mechanism is overwhelmed in heart failure. Pulmonary and peripheral oedema occurs because of high left and right atrial pressures, and is compounded by sodium and water retention, caused by impairment of renal perfusion and by secondary hyperaldosteronism. If the underlying cause is a myocardial infarction, cardiac contractility is impaired and SNS and RAAS activation causes hypertrophy of non-infarcted segments, with thinning, dilatation and expansion of the infarcted segment. This leads to further deterioration in ventricular function and worsening heart failure.
High-output failure

Sometimes cardiac failure can occur in patients without heart disease due to a large arteriovenous shunt, or where there is an excessively high cardiac output due to beri-beri (p. 714), severe anaemia or thyrotoxicosis.

Valvular disease

Heart failure can also be caused by valvular disease in which there is impaired filling of the ventricles due to mitral or tricuspid stenosis; where there is obstruction to ventricular outflow, as occurs in aortic and tricuspid stenosis and hypertrophic cardiomyopathy; or as the result of ventricular overload secondary to valvular regurgitation.

Clinical assessment

Heart failure may develop suddenly, as in MI, or gradually, as in valvular heart disease. When there is gradual impairment of cardiac function, several compensatory changes take place. The term compensated heart failure is sometimes used to describe the condition of those with impaired cardiac function, in whom adaptive changes have prevented the development of overt heart failure. However, a minor event, such as an intercurrent infection or development of atrial fibrillation, may precipitate acute heart failure in these circumstances (Box 16.13). Similarly, acute heart failure sometimes supervenes as the result of a decompensating episode, on a background of chronic heart failure; this is called acute-on-chronic heart failure.

Acute left heart failure

Acute left heart failure presents with a sudden onset of dyspnoea at rest that rapidly progresses to acute respiratory distress, orthopnoea and prostration. Often there is a clear precipitating factor, such as an acute MI, which may be apparent from the history. The patient appears agitated, pale and clammy. The peripheries are cool to the touch and the pulse is rapid, but in some cases there may be an inappropriate bradycardia that may contribute to the acute episode of heart failure. The BP is usually high because of SNS activation, but may be normal or low if the patient is in cardiogenic shock.

The jugular venous pressure (JVP) is usually elevated, particularly with associated fluid overload or right heart failure. In acute heart failure, there has been no time for ventricular dilatation and the apex is not displaced. A ‘gallop’ rhythm, with a third heart sound, is heard quite early in the development of acute left-sided heart failure. A new systolic murmur may signify acute mitral regurgitation or ventricular septal rupture. Chest examination may reveal crepitations at the lung bases if there is pulmonary oedema, or crepitations throughout the lungs if this is severe. There may be an expiratory wheeze. Patients with acute-on-chronic heart failure may have additional features of chronic heart failure (see below). Potential precipitants, such as an upper respiratory tract infection or inappropriate cessation of diuretic medication, may be identified on clinical examination or history-taking.

Chronic heart failure

Patients with chronic heart failure commonly follow a relapsing and remitting course, with periods of stability and episodes of decompensation, leading to worsening symptoms that may necessitate hospitalisation. The clinical picture depends on the nature of the underlying heart disease, the type of heart failure that it has evoked, and the changes in the SNS and RAAS that have developed (see Box 16.12 and Fig. 16.26).

Low cardiac output causes fatigue, listlessness and a poor effort tolerance; the peripheries are cold and the BP is low. To maintain perfusion of vital organs, blood flow is diverted away from skeletal muscle and this may contribute to fatigue and weakness. Poor renal perfusion leads to oliguria and uraemia.

Pulmonary oedema due to left heart failure presents with dyspnoea and inspiratory crepitations over the lung bases. In contrast, right heart failure produces a high JVP with hepatic congestion and dependent peripheral oedema. In ambulant patients the oedema affects the ankles, whereas in bed-bound patients it collects around the thighs and sacrum. Ascites or pleural effusion may occur (Fig. 16.26). Heart failure is not the only cause of oedema (Box 16.14).

Factors that may precipitate or aggravate heart failure in pre-existing heart disease

- Myocardial ischaemia or infarction
- Intercurrent illness
- Arrhythmia
- Inappropriate reduction of therapy
- Administration of a drug with negative inotropic (β-blocker) or fluid-retaining properties (non-steroidal anti-inflammatory drugs, glucocorticoids)
- Pulmonary embolism
- Conditions associated with increased metabolic demand (pregnancy, thyrotoxicosis, anaemia)
- Intravenous fluid overload

Differential diagnosis of peripheral oedema

- Cardiac failure: right or combined left and right heart failure, pericardial constriction, cardiomyopathy
- Chronic venous insufficiency: varicose veins
- Hypoalbuminaemia: nephrotic syndrome, liver disease, protein-losing enteropathy; often widespread, can affect arms and face
- Drugs:
  - Sodium retention: fludrocortisone, non-steroidal anti-inflammatory drugs
  - Increasing capillary permeability: nifedipine, amlodipine
- Idiopathic: women > men
- Chronic lymphatic obstruction
Chronic heart failure is sometimes associated with marked weight loss (cardiac cachexia), caused by a combination of anorexia and impaired absorption due to gastrointestinal congestion, poor tissue perfusion due to a low cardiac output, and skeletal muscle atrophy due to immobility.

**Complications of heart failure**

Several complications may occur in advanced heart failure, as described below.

- **Renal failure** is caused by poor renal perfusion due to low cardiac output and may be exacerbated by diuretic therapy, ACE inhibitors and angiotensin receptor blockers (ARBs).

- **Hypokalaemia** may be the result of treatment with potassium-losing diuretics or hyperaldosteronism caused by activation of the renin–angiotensin system and impaired aldosterone metabolism due to hepatic congestion. Most of the body’s potassium is intracellular and there may be substantial depletion of potassium stores, even when the plasma concentration is in the reference range.

- **Hyperkalaemia** may be due to the effects of drugs that promote renal resorption of potassium, in particular the combination of ACE inhibitors, ARBs and mineralocorticoid receptor antagonists. These effects are amplified if there is renal dysfunction due to low cardiac output or atherosclerotic renal vascular disease.

- **Hyponatraemia** is a feature of severe heart failure and is a poor prognostic sign. It may be caused by diuretic therapy, inappropriate water retention due to high vasopressin secretion, or failure of the cell membrane ion pump.

- **Impaired liver function** is caused by hepatic venous congestion and poor arterial perfusion, which frequently cause mild jaundice and abnormal liver function tests; reduced synthesis of clotting factors can make anticoagulant control difficult.

- **Thromboembolism.** Deep vein thrombosis and pulmonary embolism may occur due to the effects of a low cardiac output and enforced immobility. Systemic emboli occur in patients with atrial fibrillation or flutter, or with intracardiac thrombus complicating conditions such as mitral stenosis, MI or left ventricular aneurysm.

- **Atrial and ventricular arrhythmias** are very common and may be related to electrolyte changes such as hypokalaemia and hypomagnesaemia, the underlying cardiac disease, and the pro-arrhythmic effects of sympathetic activation. Atrial fibrillation occurs in approximately 20% of patients with heart failure and causes further impairment of cardiac function. Ventricular ectopic beats and runs of non-sustained ventricular tachycardia are common findings in patients with heart failure and are associated with an adverse prognosis.

- **Sudden death** occurs in up to 50% of patients with heart failure and is most probably due to ventricular fibrillation.

**Investigations**

A chest X-ray should be performed in all cases. This may show abnormal distension of the upper lobe pulmonary veins with the patient in the erect position (Fig. 16.27). Vascularity of the lung fields becomes more prominent and the right and left pulmonary arteries dilate. Subsequently, interstitial oedema causes thickened interlobular septa and dilated lymphatics. These are evident as horizontal lines in the costophrenic angles (septal or ‘Kerley B’ lines). More advanced changes due to alveolar oedema cause a hazy opacification spreading from the hilar regions, and pleural effusions. Echocardiography is very useful and should be considered in all patients with heart failure in order to:

- determine the aetiology

- detect hitherto unsuspected valvular heart disease, such as occult mitral stenosis, and other conditions that may be amenable to specific remedies

- identify patients who will benefit from long-term drug therapy.

Serum urea, creatinine and electrolytes, haemoglobin and thyroid function may help to establish the nature and severity of the underlying heart disease and detect any complications. BNP is elevated in heart failure and is a prognostic marker, as well as being useful in differentiating heart failure from other causes of breathlessness or peripheral oedema.

**Management of acute heart failure**

Acute heart failure with pulmonary oedema is a medical emergency that should be treated urgently. The patient should initially be kept rested, with continuous monitoring of cardiac rhythm, BP and
cardiac output, particularly in hypotensive patients. Insertion is discussed below. Following management of the acute episode, additional measures with acute cardiogenic pulmonary oedema and shock. of an intra-aortic balloon pump may be beneficial in patients accordingly.

Diuretics promote urinary sodium and water excretion, leading to a reduction in blood plasma volume (p. 354), which in turn reduces preload and improves pulmonary and systemic venous congestion. They may also reduce afterload and ventricular volume, leading to a fall in ventricular wall tension and increased cardiac efficiency. Although a fall in preload (ventricular filling pressure) normally reduces cardiac output, patients with heart failure are beyond the apex of the Starling curve, so there may be a substantial and beneficial fall in filling pressure with either no change or an improvement in cardiac output (see Figs 16.24 and 16.28). Nevertheless, the dose of diuretics needs to be titrated carefully so as to avoid excessive volume depletion, which can cause a fall in cardiac output with hypotension, lethargy and renal failure. This is especially likely in patients with a marked diastolic component to their heart failure.

Oedema may persist, despite oral loop diuretic therapy, in some patients with severe chronic heart failure, particularly with severe congestive heart failure (see Figs 16.24 and 16.28). Nevertheless, the dose of diuretics needs to be titrated carefully so as to avoid excessive volume depletion, which can cause a fall in cardiac output with hypotension, lethargy and renal failure. This is especially likely in patients with a marked diastolic component to their heart failure.

### Management of Chronic Heart Failure

The aims of treatment in chronic heart failure are to improve cardiac function by increasing contractility, optimising preload or decreasing afterload, and controlling cardiac rate and rhythm (see Fig. 16.25). This can be achieved by a combination of drug treatment or non-drug treatments, as discussed below.

#### Education

Education of patients and their relatives about the causes and treatment of heart failure can improve adherence to a management plan (Box 16.16). Some patients may need to weigh themselves daily, as a measure of fluid load, and adjust their diuretic therapy accordingly.

#### Drug Treatment

A wide variety of drug treatments are now available for the treatment of heart failure. Drugs that reduce preload are appropriate in patients with high end-diastolic filling pressures and evidence of pulmonary or systemic venous congestion, whereas those that reduce afterload or increase myocardial contractility are more useful in patients with signs and symptoms of a low cardiac output.

#### Diuretics

Diuretics promote urinary sodium and water excretion, leading to a reduction in blood plasma volume (p. 354), which in turn reduces preload and improves pulmonary and systemic venous congestion. They may also reduce afterload and ventricular volume, leading to a fall in ventricular wall tension and increased cardiac efficiency. Although a fall in preload (ventricular filling pressure) normally reduces cardiac output, patients with heart failure are beyond the apex of the Starling curve, so there may be a substantial and beneficial fall in filling pressure with either no change or an improvement in cardiac output (see Figs 16.24 and 16.28). Nevertheless, the dose of diuretics needs to be titrated carefully so as to avoid excessive volume depletion, which can cause a fall in cardiac output with hypotension, lethargy and renal failure. This is especially likely in patients with a marked diastolic component to their heart failure.

Oedema may persist, despite oral loop diuretic therapy, in some patients with severe chronic heart failure, particularly if there is renal impairment. Under these circumstances an intravenous infusion of furosemide (5–10 mg/hr) may initiate a diuresis. Combining a loop diuretic with a thiazide diuretic such as bendroflumethiazide (5 mg daily) may also prove effective but care must be taken to avoid an excessive diuresis.

Mineralocorticoid receptor antagonists, such as spironolactone and eplerenone, are potassium-sparing diuretics that are of particular benefit in patients with heart failure with severe left ventricular systolic dysfunction. They have been shown to improve long-term clinical outcome in individuals with severe heart failure or heart failure following acute MI but may cause hyperkalaemia, particularly when used with an ACE inhibitor.

### Figures

**Fig. 16.28 The effect of treatment on ventricular performance curves in heart failure.** Diuretics and venodilators (A), angiotensin-converting enzyme (ACE) inhibitors and mixed vasodilators (B), and positive inotropic agents (C).
**Angiotensin-converting enzyme inhibitors** ACE inhibitors play a central role in the management of heart failure since they interrupt the vicious circle of neurohumoral activation that is characteristic of the disease by preventing the conversion of angiotensin I to angiotensin II. This, in turn, reduces peripheral vasoconstriction, activation of the sympathetic nervous system (Fig. 16.29), and salt and water retention due to aldosterone release, as well as preventing the activation of the renin-angiotensin system caused by diuretic therapy.

In moderate and severe heart failure, ACE inhibitors can produce a substantial improvement in effort tolerance and in mortality. They can also improve outcome and prevent the onset of overt heart failure in patients with poor residual left ventricular function following MI.

Adverse effects of ACE inhibitors include symptomatic hypotension and impairment of renal function, especially in patients with bilateral renal artery stenosis or those with pre-existing renal disease. An increase in serum potassium concentration may also occur, which can be beneficial in offsetting the hypokalaemia associated with loop diuretic therapy. Short-acting ACE inhibitors can cause marked falls in BP, particularly in the elderly or when started in the presence of hypotension, hypovolaemia or hyponatraemia. In stable patients without hypotension (systolic BP over 100 mmHg), ACE inhibitors can usually be safely started in the community. In other patients, however, it is usually advisable to withhold diuretics for 24 hours before starting treatment with a small dose of a long-acting agent, preferably given at night (Box 16.18). Renal function and serum potassium must be monitored and should be checked 1–2 weeks after starting therapy.

**Angiotensin receptor blockers** ARBs act by blocking the action of angiotensin II on the heart, peripheral vasculature and kidney. In heart failure, they produce beneficial haemodynamic changes that are similar to the effects of ACE inhibitors (Fig. 16.29) but are generally better tolerated. They have comparable effects on mortality and are a useful alternative for patients who cannot tolerate ACE inhibitors. Like ACE inhibitors they should be started at a low dose and titrated upwards, depending on response (Box 16.18). Unfortunately, they share all the more serious adverse effects of ACE inhibitors, including renal dysfunction and hyperkalaemia. ARBs are normally used as an alternative to ACE inhibitors, but the two can be combined in patients with resistant or recurrent heart failure.

**Neprilysin inhibitors** The only drug currently in this class is sacubitril, a small-molecule inhibitor of neprilysin, which is

#### 16.17 Congestive cardiac failure in old age

- **Incidence**: rises with age and affects 5–10% of those in their eighties.
- **Common causes**: coronary artery disease, hypertension and calcific degenerative valvular disease.
- **Diastolic dysfunction**: often prominent, particularly in those with a history of hypertension.
- **ACE inhibitors**: improve symptoms and mortality but are more frequently associated with postural hypotension and renal impairment than in younger patients.
- **Loop diuretics**: usually required but may be poorly tolerated in those with urinary incontinence and men with prostate enlargement.

Fig. 16.29 Neurohumoral activation and sites of action of drugs used in the treatment of heart failure.
Vasodilators These drugs are valuable in chronic heart failure, when ACE inhibitors or ARBs are contraindicated. Venodilators, such as nitrates, reduce preload, and arterial dilators, such as hydralazine, reduce afterload (see Fig. 16.28). Their use is limited by pharmacological tolerance and hypotension.

Beta-adrenoceptor blockers Beta-blockade helps to counteract the deleterious effects of enhanced sympathetic stimulation and reduces the risk of arrhythmias and sudden death. When initiated in standard doses β-blockers may precipitate acute-on-chronic heart failure, but when given in small incremental doses they can increase ejection fraction, improve symptoms, reduce the frequency of hospitalisation and reduce mortality in patients with chronic heart failure. A typical regimen is bisoprolol, starting at a dose of 1.25 mg daily and increased gradually over a 12-week period to a target maintenance dose of 10 mg daily. Beta-blockers are more effective at reducing mortality than ACE inhibitors, with a relative risk reduction of 33% versus 20%, respectively.

Ivabradine Ivabradine acts on the I, inward current in the SA node, resulting in reduction of heart rate. It reduces hospital admission and mortality rates in patients with heart failure due to moderate or severe left ventricular systolic impairment. In trials, its effects were most marked in patients with a relatively high heart rate (over 77/min), so ivabradine is best suited to patients who cannot take β-blockers or whose heart rate remains high despite β-blockade. It is ineffective in patients with atrial fibrillation.

Digoxin Digoxin (p. 482) can be used to provide rate control in patients with heart failure and atrial fibrillation. In patients with severe heart failure (NYHA class III–IV, see Box 16.5), digoxin reduces the likelihood of hospitalisation for heart failure, although it has no effect on long-term survival.

Amiodarone This is a potent anti-arrhythmic drug (p. 481) that has little negative inotropic effect and may be valuable in patients with poor left ventricular function. It is effective only in the treatment of symptomatic arrhythmias and should not be used as a preventative agent in asymptomatic patients. Amiodarone is used for prevention of symptomatic atrial arrhythmias and of ventricular arrhythmias when other pharmacological options have been exhausted.

Non-pharmacological treatments

Implantable cardiac defibrillators These devices are indicated in patients with symptomatic ventricular arrhythmias and heart failure, since they improve prognosis and survival (p. 483).

Resynchronisation devices In patients with marked intraventricular conduction delay, prolonged depolarisation may lead to uncoordinated left ventricular contraction. When this is associated with severe symptomatic heart failure, cardiac resynchronisation devices may be helpful. Here, both the LV and RV are paced simultaneously (Fig. 16.30) to generate a more coordinated left ventricular contraction and improve cardiac output. This is associated with improved symptoms and survival.

Coronary revascularisation Coronary artery bypass surgery or percutaneous coronary intervention may improve function in areas of the myocardium that are ‘hibernating’ because of inadequate blood supply, and can be used to treat carefully selected patients with heart failure and coronary artery disease. If necessary, ‘hibernating’ myocardium can be identified by stress echocardiography and specialised nuclear or magnetic resonance imaging.

Cardiac transplantation Cardiac transplantation is an established and successful treatment for patients with intractable heart failure. Coronary artery disease and dilated cardiomyopathy are the most common indications. The use of transplantation is limited by the efficacy of modern drug and device therapies, as well as the availability of donor hearts, so it is generally reserved for young patients with severe symptoms despite optimal therapy. Conventional heart transplantation is contraindicated in patients with pulmonary vascular disease due to long-standing left heart failure, complex congenital heart disease such as Eisenmenger’s syndrome, or primary pulmonary hypertension because the RV of the donor heart may fail in the face of high pulmonary vascular resistance. However, heart–lung transplantation can be successful in patients with Eisenmenger’s syndrome, and lung transplantation has been used for primary pulmonary hypertension.

Although cardiac transplantation usually produces a dramatic improvement in the recipient’s quality of life, serious complications may occur:

- Rejection, In spite of routine therapy with ciclosporin A, azathioprine and glucocorticoids, episodes of rejection are common and may present with heart failure, arrhythmias or subtle ECG changes. Cardiac biopsy is often used to confirm the diagnosis before starting treatment with high-dose glucocorticoids.

- Accelerated atherosclerosis. Recurrent heart failure is often due to progressive atherosclerosis in the coronary arteries of the donor heart. This is not confined to patients who underwent transplantation for coronary artery disease and is probably a manifestation of chronic rejection. Angina is rare because the heart has been denervated.
Cardiac arrhythmias

A cardiac arrhythmia is defined as a disturbance of the electrical rhythm of the heart. Cardiac arrhythmias are often a manifestation of structural heart disease but may also occur because of abnormal conduction or depolarisation in an otherwise healthy heart. There are many types of cardiac arrhythmia, as discussed later in this section. By convention, however, a heart rate of more than 100/min is called a tachycardia, and a heart rate of less than 60/min is called a bradycardia.

Pathogenesis

Cardiac arrhythmias usually occur as the result of pathology affecting the conduction system of the heart. The cardiac cycle is normally initiated by an electrical discharge from the SA node. The atria and ventricles then activate sequentially as electrical depolarisation passes through specialised conducting tissues (see Fig. 16.4, p. 445). The sinus node acts as a pacemaker and its intrinsic rate is regulated by the autonomic nervous system; vagal activity decreases the heart rate and sympathetic activity increases heart rate through cardiac sympathetic nerves and circulating catecholamines.

There are three main mechanisms of tachycardia:

- **Increased automaticity.** The tachycardia is produced by spontaneous depolarisation of an ectopic focus in the atria, atrioventricular junction or ventricles, often in response to catecholamines. Single depolarisations lead to atrial, junctional or ventricular premature (ectopic) beats. Repeated depolarisation leads to atrial, junctional or ventricular tachycardia.
- **Re-entry.** The tachycardia is initiated by an ectopic beat and sustained by a re-entry circuit (Fig. 16.31). Most tachyarrhythmias are caused by re-entry.
- **Triggered activity.** This can cause ventricular arrhythmias in patients with coronary artery disease. It is a form of secondary depolarisation arising from an incompletely repolarised cell membrane. Arrhythmias may be supraventricular (sinus, atrial or junctional) or ventricular in origin.

Supraventricular rhythms usually produce narrow QRS complexes because the ventricles are depolarised in their normal sequence via the AV node, the bundle of His and associated Purkinje fibres. In contrast, ventricular rhythms produce broad, bizarre QRS complexes because the ventricles are activated in an abnormal sequence. Occasionally, supraventricular tachycardia can mimic ventricular tachycardia and present as a broad-complex tachycardia due to coexisting bundle branch block or the presence of an additional atrioventricular connection (accessory pathway, see below).

Bradycardia may be due to reduced automaticity of the SA node or abnormalities of conduction through the AV node. If the sinus rate becomes unduly slow, another, more distal part of the conducting system may assume the role of pacemaker. This is known as an escape rhythm and may arise in the AV node or His bundle (junctional rhythm) or in the ventricles (idioventricular rhythm).

Clinical features

Many arrhythmias are asymptomatic but sustained tachycardias typically present with rapid palpitation, dizziness, chest discomfort or breathlessness. Extreme tachycardias can also cause syncope because the heart is unable to contract or relax properly at extreme rates. Bradycardias tend to cause symptoms that reflect low cardiac output, including fatigue, lightheadedness and syncope. Extreme bradycardias or tachycardias can precipitate sudden death or cardiac arrest.

Investigations

The first-line investigation is a standard 12-lead ECG, which can be diagnostic in many cases. If arrhythmias are intermittent and the resting ECG is normal, an attempt should be made to capture the abnormal rhythm using an ambulatory ECG or a patient-activated ECG.

**Fig. 16.31** The mechanism of re-entry. Re-entry can occur when there are two alternative pathways with different conducting properties, such as the atrioventricular node and an accessory pathway, or an area of normal and an area of ischaemic tissue. Here, pathway A conducts slowly and recovers quickly, while pathway B conducts rapidly and recovers slowly. (1) In sinus rhythm, each impulse passes down both pathways before entering a common distal pathway. (2) As the pathways recover at different rates, a premature impulse may find pathway A open and B closed. (3) Pathway B may recover while the premature impulse is travelling selectively down pathway A. The impulse can then travel retrogradely up pathway B, setting up a closed loop or re-entry circuit. (4) This may initiate a tachycardia that continues until the circuit is interrupted by a change in conduction rates or electrical depolarisation.
Management

Features of individual arrhythmias are discussed below. Management depends on the nature of the arrhythmia and the general principles of medical management are discussed on page 479.

Sinus arrhythmia

This is defined as a cyclical alteration of the heart rate during respiration, with an increase during inspiration and a decrease during expiration. Sinus arrhythmia is a normal phenomenon and can be quite pronounced in children. Absence of this normal variation in heart rate with breathing or with changes in posture may be a feature of diabetic neuropathy (p. 758), autonomic involvement in patients with diseases of peripheral nerves (p. 1138) or increased sympathetic drive. Sinus arrhythmia does not require treatment.

Sinus bradycardia

This may occur in healthy people at rest and is a common finding in athletes. Some pathological causes are listed in Box 16.19. If sinus bradycardia is asymptomatic, then no treatment is required. Symptomatic sinus bradycardia may occur acutely during an MI and can be treated with intravenous atropine (0.6–1.2 mg). Patients with recurrent or persistent symptomatic sinus bradycardia should be considered for pacemaker implantation.

Sinus tachycardia

Sinus tachycardia is usually due to an increase in sympathetic activity associated with exercise, emotion and pregnancy. Healthy young adults can produce a rapid sinus rate, up to 200/min, during intense exercise. Sinus tachycardia does not require treatment but sometimes may reflect an underlying disease, as summarised in Box 16.19.

Sick sinus syndrome

Sick sinus syndrome can occur at any age but is most common in older people. It is caused by fibrosis, degenerative changes or ischaemia of the SA node and is characterised by a variety of arrhythmias (Box 16.20). The typical presentation is with palpitation, dizzy spells or syncope, due to intermittent tachycardia, bradycardia, or pauses with no atrial or ventricular activity (SA block or sinus arrest) (Fig. 16.32).

A permanent pacemaker may benefit patients with troublesome symptoms due to spontaneous bradycardias, or those with symptomatic bradycardias induced by drugs required to prevent tachyarrhythmias. Atrial pacing may prevent episodes of atrial fibrillation. Pacing improves symptoms but not prognosis, and is not indicated in patients who are asymptomatic.

Atrial ectopic beats
